#### Abstract

This paper attempts to document and account for the long run evolution of inheritance. We find that in a country like France the annual flow of inheritance was about $20 \%-25 \%$ of national income between 1820 and 1910, down to less than $5 \%$ in 1950, and back up to about $15 \%$ by 2010. A simple theoretical model of wealth accumulation, growth and inheritance can fully account for the observed U-shaped pattern and levels. Using this model, we find that under plausible assumptions the annual bequest flow might reach about 20\%-25\% of national income by 2050. This corresponds to a capitalized bequest share in total wealth accumulation well above $100 \%$. Our findings illustrate the fact that when the growth rate $g$ is small, and when the rate of return to private wealth $r$ is permanently and substantially larger than the growth rate (say, $r=4 \%-5 \%$ vs. $g=1 \%-2 \%$ ), which was the case in the $19^{\text {th }}$ century and early $20^{\text {th }}$ century and is likely to happen again in the $21^{\text {st }}$ century, then past wealth and inheritance are bound to play a key role for aggregate wealth accumulation and the structure of lifetime inequality. Contrarily to a widely spread view, modern economic growth did not kill inheritance.

## 1. Introduction

There are basically two ways to become rich: either through one's own work, or through inheritance. In Ancien Regime societies, as well as during the $19^{\text {th }}$ century and early $20^{\text {th }}$ century, it was self-evident to everybody that the inheritance channel was an important one. For instance, 19th century and early $20^{\text {th }}$ century novels are full of stories where ambitious young men have to choose between becoming rich through their own work or by marrying a bride with large inherited wealth - and often opt for the second strategy. However, in the late $20^{\text {th }}$ century and early $21^{\text {st }}$ century, most observers seem to believe that this belongs to the past. That is, most observers - novelists, economists and laymen alike - tend to assume that labor income is now playing a much bigger role than inherited wealth in shaping people's lives, and that human capital and hard work have become the key to personal material well-being. Although this is rarely formulated explicitly, the implicit assumption seems to be that the structure of modern economic growth has led to the rise of human capital, the decline of inheritance, and the triumph of meritocracy.

This paper asks a simple question: is this optimistic view of economic development justified empirically and well-grounded theoretically? Our simple answer is "no". Our empirical and theoretical findings suggest that inherited wealth will most likely play as big a role in $21^{\text {st }}$ century capitalism as it did in $19^{\text {th }}$ century capitalism - at least from an aggregate viewpoint.

This paper makes two contributions. First, by combining various data sources in a systematic manner, we document and establish a simple - but striking - fact: the aggregate inheritance flow has been following a very pronounced U-shaped pattern in France since the $19^{\text {th }}$ century. To our knowledge, this is the first time that such long-run, homogenous inheritance series are constructed for any country.

More precisely, we define the annual inheritance flow as the total market value of all assets (tangible and financial assets, net of financial liabilities) transmitted at death or through inter-vivos gifts during a given year. ${ }^{1}$ We find that the annual inheritance flow was about $20 \%-25 \%$ of national income around 1900-1910. It then gradually fell to less than

[^2]10\% in the 1920s-1930s, and to less than 5\% in the 1950s. It has been rising regularly since then, with an acceleration of the trend during the past 30 years, and according to our latest data point (2008), it is now close to $15 \%$ (see Figure 1).

If we take a longer run perspective, then the $20^{\text {th }}$ century U-shaped pattern looks even more spectacular. The inheritance flow was relatively stable around $20 \%-25 \%$ of national income throughout the 1820-1910 period (with a slight upward trend), before being divided by a factor of about 5-6 between 1910 and the 1950s, and then multiplied by a factor of about 3-4 between the 1950s and the 2000s (see Figure 2).

These are truly enormous historical variations - but they appear to be well founded empirically. In particular, we find similar patterns with our two fully independent estimates of the inheritance flow. The gap between our "economic flow" series (computed from national wealth estimates, mortality tables and observed age-wealth profiles) and our "fiscal flow" series (computed from observed bequest and gift tax data) can be interpreted as a measure of tax evasion and other measurement errors. This gap appears to approximately constant over time, and relatively small, so that our two series deliver fairly consistent long run patterns (see Figures $1 \& 2$ ).

If we use personal disposable income (national income minus taxes plus cash transfers) rather than national income as the denominator, then we find that the inheritance flow observed in the early $21^{\text {st }}$ century is back to about $20 \%$, i.e. approximately the same level as that observed one century ago (see Figure 3). This simply comes from the fact that disposable income was as high as $90 \%-95 \%$ of national income during the $19^{\text {th }}$ century and early $20^{\text {th }}$ century (when taxes and transfers were almost non existent), while it is now about $70 \%$ of national income. Though we prefer to use the national income denominator (both for conceptual and empirical reasons), ${ }^{2}$ this is an important fact to keep in mind when studying these issues. An annual inheritance flow around $20 \%$ of disposable income

[^3]is a very large flow. It is typically larger than the annual flow of new savings, and almost as big as the annual flow of capital income. As we shall see, it corresponds to a cumulated, capitalized bequest share in aggregate wealth accumulation well above $100 \%$.

The second - and most important - contribution of this paper is to account for these facts, and to draw lessons for other countries and for the future. We show that a simple theoretical model of wealth accumulation, growth and inheritance can easily explain why the French inheritance flow seems to return to a high steady-state value around $20 \%$ of national income. Consider first a dynastic model where all savings come from capital income. Wealth holders save a fraction $\mathrm{g} / \mathrm{r}$ of their asset returns, so that aggregate private wealth $W_{t}$ and national income $Y_{t}$ grow at the same rate $g$, and the wealth-income ratio $\beta=W_{t} / Y_{t}$ is stationary. It is straightforward to prove that the steady-state inheritance flownational income ratio is equal to $b_{y}=\beta / H$, where $H$ is generation length (average age at parenthood). If $\beta=600 \%$ and $H=30$, then $b_{y}=20 \%$. We show that this intuition can be generalized to more general saving models. Namely, as long as the (real) growth rate $g$ is sufficiently small and the (real) rate of return on private wealth $r$ is sufficiently large - say, $g=1 \%-2 \%$ vs. $r=4 \%-5 \%-$, then steady-state $b_{y}$ is close to the class saving level $\beta / H$.

The key intuition boils down to a simple $r>g$ logic. In countries with large growth, such as France during the 1950s-1970s, then wealth coming from the past (i.e. accumulated or received by one's parents or grand-parents, who were relatively poor as compared to today's incomes) does not matter too much. What counts is new wealth accumulated out of current income. Inheritance flows are bound to be a small fraction of national income. But in countries with low growth, such as France in the $19^{\text {th }}$ century and since the 1970s, the logic is reversed. With low growth, successors simply need to save a small fraction of their asset returns in order to ensure that their inherited wealth grows at least as fast as national income. In effect, $g$ small and $r>g$ imply that wealth coming from the past is being capitalized at a faster rate than national income. So past wealth tends to dominate new wealth, rentiers tend to dominate labor income earners, and inheritance flows are large relative to national income. As $g \rightarrow 0$, then $b_{y} \rightarrow \beta / H$ - irrespective of saving behavior.

The $r>g$ logic is simple, but powerful. We simulate a full-fledged, out-of-steady-state version of this model, using observed macroeconomic and demographic shocks. We are able to reproduce remarkably well the observed evolution of inheritance flows in France over almost two centuries. The 1820-1913 period looks like a prototype low-growth,
rentier-friendly quasi-steady-state. The growth rate was very small: $\mathrm{g}=1.0 \%$. The wealthincome ratio $\beta$ was $600 \%-700 \%$, the capital share $\alpha$ was $30 \%-40 \%$, so the average rate of return on private wealth was as large as $r=\alpha / \beta=5 \%-6 \%$. Taxes at that time were very low, so after-tax returns were almost as high as pre-tax returns. It was sufficient for successors to save about $20 \%$ of their asset returns to ensure that their wealth grows as fast as national income (or actually slightly faster). The inheritance flow was close to its steadystate value $b_{y}=\beta / H=20 \%-25 \%$. The 1914-1945 capital shocks (involving war destructions, and most importantly a prolonged fall in asset prices) clearly dismantled this steady-state. It took a long time for inheritance flows to recover, especially given the exceptionally high growth rates observed during the 1950s-1970s ( $\mathrm{g}=5.2 \%$ between 1949 and 1979). The recovery accelerated since the late 1970s, both because of low growth ( $\mathrm{g}=1.7 \%$ between 1979 and 2009), and because of the long term recovery of asset prices and of the wealthincome ratio ( $\beta=500 \%-600 \%$ in 2008-9). As predicted by the theoretical model, the inheritance flow is now close to its steady-state value $b_{y}=\beta / H=15 \%-20 \%$.

We then use this model to predict the future. According to our benchmark scenario, based upon current growth rates and rates of returns, the inheritance flow will stabilize around $16 \%$ of national income by 2040 , i.e. at a lower level than the $19^{\text {th }}$ century steady-state. This is due both to higher projected growth rates (1.7\% rather than $1.0 \%$ ) and to lower projected after-tax rates of return ( $3.0 \%$ rather than $5.3 \%$ ). In case growth slows down to $1.0 \%$ after 2010, and after-tax returns rise to $5.0 \%$ (which corresponds to the suppression of all capital taxes, and/or to a combination of capital tax cuts and a rising global capital share), then the model predicts that the inheritance flow will keep rising and converge towards $22 \%-23 \%$ after 2050. In all plausible scenarios, the inheritance-income ratio in the coming decades will be at least $15 \%-20 \%$, i.e. closer to the $19^{\text {th }}$ century levels than to the exceptionally low levels prevailing during the 1950s-1970s. A come-back to postwar levels would require pretty extreme assumptions, such as the combination of high growth rates (above $5 \%$ ) and a prolonged fall in asset prices and aggregate wealth-income ratios.

Now, the fact that aggregate inheritance flows return to $19^{\text {th }}$ century levels obviously does not imply that the concentration of inheritance and wealth will return to $19^{\text {th }}$ century levels. On distributional issues, this macro paper has very little to say. We view the present research mostly as a positive exercise in aggregate accounting of wealth, income and inheritance, and as a building block for future work on inequality. One should however bear in mind that the historical decline of wealth concentration in developed societies has
been quantitatively less important than some observers tend to imagine. E.g. according to the latest SCF (Survey of consumer finances), the top $10 \%$ owns $72 \%$ of U.S. aggregate wealth in 2007, while the middle $40 \%$ owns $26 \%$ and the bottom $50 \%$ owns $2 \% .^{3}$ In a country like France, the top $10 \%$ currently owns about $60 \%$ of aggregate wealth, and the bottom $50 \%$ owns around $5 \%$. These $60 \%-70 \%$ top decile wealth shares are certainly lower than the $90 \%$ top decile wealth shares observed in developed countries around 1900-1910, when there was basically no middle class at all. ${ }^{4}$ But they are not that much lower. It has also been known for a long time that these high levels of wealth concentration have little to do with the life cycle: top wealth shares are almost as large within each age group. ${ }^{5}$ The bottom line is that the historical decline in intra-cohort inequality of inherited wealth has been less important quantitatively than the long term changes in the aggregate inheritance-income ratio. So aggregate evolutions matter a lot for the study of inequality.

In order to illustrate this point, we provide applications of our aggregate findings to the measurement of two-dimensional inequality in lifetime resources (labor income vs inheritance) by cohort. By making approximate assumptions on intra cohort distributions, we compute simple two-dimensional inequality indicators, and we find that they have changed a lot over the past two centuries. In the $19^{\text {th }}$ century, top successors vastly dominated top labor earners (not to mention bottom labor earners) in terms of total lifetime resources. Cohorts born in the 1900s-1950s faced very different life opportunities. For the first time maybe in history, high labor income was the key for high material well-being. According to our computations, cohorts born in the 1970s and after will fall somewhere in between the "rentier society" of the $19^{\text {th }}$ century and the "meritocratic society" of the $20^{\text {th }}$ century - and in many ways will be closer to the former than to the latter.

Do our findings also apply to other countries? We certainly do not pretend that the fairly specific U-shaped pattern of aggregate inheritance flows found for France applies everywhere as a universal law. It probably also applies to Continental European countries that were hit by similar growth and capital shocks. For countries like the U.S. and the U.K., which were little hit by war destructions, but suffered from the same mid-century fall in asset prices, the long-run U-shaped pattern of aggregate inheritance flows was possibly

[^4]somewhat less pronounced. ${ }^{6}$ In fact, we do not really know. We tried to construct similar series for other countries. But unfortunately there does not seem to exist any other country with estate tax data that is as long run and as comprehensive as the French data.

In any case, even though we cannot make detailed cross country comparisons at this stage, the economic mechanisms revealed by the analysis of the French historical experience certainly apply to other countries as well. In particular, the r>g logic applies everywhere, and has important implications. For instance, it implies that in countries with very large economic and/or demographic growth rates, such as China or India, inheritance flows must be a relatively small fraction of national income. Conversely, in countries with low economic growth and projected negative population growth, such as Spain, Italy or Germany, then inheritance is bound to matter a lot during the $21^{\text {st }}$ century. Aggregate inheritance flows will probably reach higher levels than in France. More generally, a major difference between the U.S. and Europe (taken as a whole) from the viewpoint of inheritance might well be that demographic (and to a lesser extent economic) growth rates have been historically larger in the U.S., thereby making inheritance flows relatively less important. This has little to do with cultural differences. This is just the mechanical impact of growth rates and of the $\mathrm{r}>\mathrm{g}$ logic. And this may not last forever. If we take a very long run, global perspective, and make the assumption that economic and demographic growth rates will eventually be relatively small everywhere (say, $g=1 \%-2 \%$ ), then the conclusion follows mechanically: inheritance will matter a lot pretty much everywhere.

The rest of this paper is organized as follows. In section 2, we relate this work to the existing literature. In section 3, we describe our methodology and data sources. In section 4, we present a decomposition of the U-shaped pattern into three components: an aggregate wealth-income effect, a mortality effect, and a relative wealth effect. In section 5 , we provide theoretical results on steady-state inheritance flows. In section 6, we report simulation results based upon a full fledged version of this model. In section 7, we present applications of our results to the structure of lifetime inequality and to the share of inheritance in aggregate wealth. Section 8 offers concluding comments.

[^5]
## 2. Related literature

### 2.1. Literature on top incomes

This paper is related to several literatures. First, this work represents in our view the logical continuation of the recent literature on the long run evolution of top income and top wealth shares initiated by Piketty (2001, 2003), Atkinson (2005) and Piketty and Saez (2003). In this collective research project, we constructed homogenous, long run series on the share of top decile and top percentile income groups in national income, using income tax return data. The resulting data base now includes annual series for over 20 countries, including most developed economies over most of the $20^{\text {th }}$ century. ${ }^{7}$ One the main findings is that the historical decline in top income shares that occurred in most countries during the first half of the $20^{\text {th }}$ century was largely due to the fall of top capital incomes, which apparently never fully recovered from the 1914-1945 shocks, possibly because of the rise of progressive income and estate taxes (the "fall of rentiers"). Another important finding is that the large rise in top income shares that occurred in the U.S. (and, to a lesser extent, in other anglo-saxon countries) since the 1970s seem to be mostly due to the unprecedented rise of very top labor incomes (the "rise of working rich").

One important limitation of this literature, however, is that although we did emphasize the distinction between top labor vs. top capital incomes, we did not go all the way towards a satisfactory decomposition of inequality between a labor income component and an inherited wealth component. First, due to various legal exemptions, a growing fraction of capital income has gradually escaped from the income tax base (which in several countries has almost become a labor income tax in recent decades), and we did not seriously attempt to impute full economic capital income (as measured by national accounts) back into our income-tax-returns-based series. ${ }^{8}$ This might seriously affect some of our conclusions (e.g. about working rich vs rentiers), ${ }^{9}$ and is likely to become

[^6]increasingly problematic in the coming decades. So it is important to develop ways to correct for this. Next, even if we were able to observe (or impute) full economic capital income, this would not tell us anything about the share of capital income coming from one's own savings and the share originating from inherited wealth. In income tax returns, one does not observe where wealth comes from. For a small numbers of countries, long run series on top wealth shares (generally based upon estate tax returns) have recently been constructed. ${ }^{10}$ These studies confirm that there was a significant decline in wealth concentration during the 1914-1945 period, apparently with no recovery so far. ${ }^{11}$ But they do not attempt to break down wealth into an inherited component and a life-cycle or selfmade component: these works use estate tax data to obtain information about the distribution of wealth among the living (using mortality multiplier techniques), but not to study the level of inheritance flows per se. ${ }^{12}$

This paper attempts to bridge this gap, by making use of the exceptionally high quality of French estate tax data. We felt that it was necessary to start by trying to reach a better empirical and theoretical understanding of the aggregate evolution of the inheritanceincome ratio, which to us was very obscure when we started this research. However the next step is obviously to close this detour via macroeconomics and to integrate endogenous distributions back into the general picture.

### 2.2. Literature on intergenerational transfers and aggregate wealth accumulation

The present paper is also very much related to the literature on intergenerational transfers and aggregate wealth accumulation. However as far we know our paper is the first attempt to account for the observed historical evolution of inheritance, and to take a long run perspective on these issues. Although the perception of a long term decline of inheritance relatively to labor income seems to be relatively widespread, to our knowledge there are

[^7]very few papers which formulate this perception explicitly. ${ }^{13}$ For instance, in their famous controversy about the share of inheritance in U.S. aggregate wealth accumulation, both Kotlikoff and Summers (1981) and Modigliani (1986) were using a single - and relatively ancient and fragile - data point for the U.S. aggregate inheritance flow (namely, for year 1962). In addition to their definitional conflict, we believe that the lack of proper data contributes to explain the intensity of the dispute, which the subsequent literature did not fully resolve. ${ }^{14}$ We return to this controversy when we use our aggregate inheritance flows series to compute inheritance shares in the total stock of wealth. The bottom line is that with steady-state inheritance flows around $20 \%$ of national income, the cumulated, capitalized bequest share in aggregate wealth accumulation is bound to be well above $100 \%$ - which in a way corroborates the Kotlikoff-Summers viewpoint. We hope that our findings contribute to clarify this long standing dispute.

### 2.3. Literature on calibrated models of wealth distributions

Our work is also related to the recent literature attempting to use calibrated general equilibrium models in order to replicate observed wealth inequality. Several authors have recently introduced new ingredients into calibrated models, such as large uninsured idiosyncratic shocks to labor earnings, tastes for savings and bequests, and/or asset returns. ${ }^{15}$ In addition to the variance and functional form of these shocks, one key driving force in these models is naturally the macroeconomic importance of inheritance flows: other things equal, larger inheritance flows tend to lead to more persistent inequalities and higher steady-state levels of wealth concentration. However this key parameter tends to be imprecisely calibrated in this literature, and is generally underestimated: it is often based upon relatively ancient data (typically dating back to the KSM controversy and using data from the 1960s-1970s) and frequently ignores inter vivos gifts. We hope that our findings can contribute to offer a stronger empirical basis for these calibrations.

[^8]
### 2.4. Literature on estate multipliers

Finally, our paper is closely related to the late $19^{\text {th }}$ century and early $20^{\text {th }}$ century literature on national wealth and the so-called "estate multiplier". At that time, many economists were computing estimates of national wealth, especially in France and in the UK. In their view, it was obvious that most wealth derives from inheritance. They were satisfied to find that their national wealth estimates $W_{t}$ (obtained from direct wealth census methods) were always approximately equal to $30-35$ times the inheritance flow $B_{t}$ (obtained from tax data). They interpreted 30-35 as generation length H , and they viewed the estate multiplier formula $e_{t}=W_{t} / B_{t}=H$ as self-evident. ${ }^{16}$ In fact, it is not self-evident. This formula is not an accounting equation, and strictly speaking it is valid only under fairly specific models of saving behaviour and wealth accumulation, such as the class saving model. It is difficult to know exactly what model the economists of the time had in mind. From their informal discussions, one can infer that it was close to a stationary model with zero growth and zero saving (in which case $\mathrm{e}_{\mathrm{t}}=\mathrm{H}$ is indeed self-evident), or maybe a model with small growth originating from slow capital accumulation and a gradual rise of the wealth-income ratio. Of course we now know that capital accumulation alone cannot generate positive self-sustained growth: one needs positive rates of productivity growth $\mathrm{g}>0$. Economists writing in the $19^{\text {th }}$ and early $20^{\text {th }}$ centuries were not fully aware of this, and they faced major difficulties with the modelling of steady-state, positive self-sustained growth. This is probably the reason why they were unable to formulate an explicit dynamic, non-stationary model explaining where the estate multiplier formula comes from.

The estate multiplier literature disappeared during the interwar period, when economists realized that the formula was not working any more, or more precisely when they realized that it was necessary to raise the multiplier $e_{t}$ to as much as 50 or 60 in order to make it work (in spite of the observed constancy of H around 30 ). ${ }^{17}$ Shortly before World War 1, a number of British and French economists also started realizing on purely logical grounds that the formula was too simplistic. They started looking carefully at age-wealth profiles, and developed the so-called "mortality multiplier" literature, whereby wealth-at-death data is being re-weighted by the inverse morality rate of the given age group in order to

[^9]generate estimates for the distribution of wealth among the living (irrespective of whether this wealth comes from inheritance or not). ${ }^{18}$ Unlike the estate multiplier formula, the mortality multiplier formula is indeed a pure accounting equation, and makes no assumption on saving behaviour. The price to pay for this is that the mortality multiplier approach does not say anything about where wealth comes from: this is simply a statistical technique to recover the cross-sectional distribution of wealth among the living. ${ }^{19}$

In the 1950s-1960s, economists then started developing the life cycle approach to wealth accumulation. ${ }^{20}$ This was in many ways the complete opposite extreme to the estate multiplier approach. In the life cycle model, inheritance plays no role at all, individuals die with zero wealth (or little wealth), and the estate multiplier $\mathrm{e}_{\mathrm{t}}=\mathrm{W}_{\mathrm{t}} / \mathrm{B}_{\mathrm{t}}$ is infinite (or very large, say 100 or more). It is interesting to note that this theory was formulated precisely at the time when inheritance was at its historical nadir. According to our series, the inheritance flows were about $4 \%$ of national income in the 1950s-1960s, vs. as much as $20 \%-25 \%$ at the time of estate multiplier economists (see Figure 2). Presumably, economists were in both cases very much influenced by the wealth accumulation and inheritance patterns prevailing at the time they wrote.

Our advantage over both estate-multiplier and life-cycle economists is that we have more years of data. Our two-century-long perspective allows us to clarify these issues and to reconcile the various approaches in a unified framework (or so we hope). The lifecycle motive for saving is logically plausible. But it clearly cohabits with many other motives for wealth accumulation (bequest, security, prestige and social status, etc.). Most importantly, we show that with low growth rates and high rates of return, past wealth naturally tends to dominate new wealth, and inheritance flows naturally tend to converge towards levels that are not too far from those posited by the estate multiplier formula, whatever the exact combination of these saving motives might be.

[^10]
## 3. Data sources and methodology

The two main data sources used in this paper are national income and wealth accounts on the one hand, and estate tax data on the other hand. Before we present these two data sources in a more detailed way, it is useful to describe the basic accounting equation that we will be using throughout the paper in order to relate national accounts and inheritance flows. In particular, this is the accounting equation that we used to compute our "economic inheritance flow" series.

### 3.1. Basic accounting equation: $B_{t} / \underline{Y}_{t}=\mu_{t} \underline{m}_{t} \underline{W}_{t} / \underline{Y}_{t}$

If there was no inter vivos gift, i.e. if all wealth transmission occurred at death, then in principle one would not need in any estate tax data in order to compute the inheritance flow. One would simply need to apply the following equation:

$$
\begin{align*}
& B_{t} / Y_{t} & =\mu_{t} m_{t} W_{t} / Y_{t} \\
\text { I.e. } & b_{y t} & =\mu_{t} m_{t} \beta_{t} \tag{3.1}
\end{align*}
$$

With: $B_{t}=$ annual inheritance flow
$Y_{t}=$ national income
$\mathrm{W}_{\mathrm{t}}=$ aggregate private wealth
$\mathrm{m}_{\mathrm{t}}=$ annual mortality rate $=$ (total number of decedents)/(total living population)
$\mu_{\mathrm{t}}=$ ratio between average wealth of the deceased and average wealth of the living
$b_{y t}=B_{t} / Y_{t}=$ aggregate inheritance flow-national income ratio
$\beta_{t}=W_{t} / Y_{t}=$ aggregate private wealth-national income ratio

Alternatively, equation (3.1) can be written in per capita terms:

$$
\begin{equation*}
\mathrm{b}_{\mathrm{t}} / \mathrm{y}_{\mathrm{t}}=\mu_{\mathrm{t}} \mathrm{w}_{\mathrm{t}} / \mathrm{y}_{\mathrm{t}}=\mu_{\mathrm{t}} \beta_{\mathrm{t}} \tag{3.2}
\end{equation*}
$$

With: $b_{t}=$ average inheritance per decedent
$y_{t}=$ average national income per living individual
$\mathrm{w}_{\mathrm{t}}=$ average private wealth per living individual

Equation (3.1) is a pure accounting equation: it does not make any assumption about behaviour or about anything. For instance, if the aggregate wealth-income ratio $\beta_{\mathrm{t}}$ is equal to $600 \%$, if the annual mortality rate $m_{t}$ is equal to $2 \%$, and if people who die have the same average wealth as the living ( $\mu_{\mathrm{t}}=100 \%$ ), then the annual inheritance flow byt has to be equal to $12 \%$ of national income. In case old-age individuals massively dissave in order to finance retirement consumption, or annuitize their assets so as to die with zero wealth, as predicted by the pure life-cycle model, then $\mu_{\mathrm{t}}=0 \%$ and $\mathrm{b}_{\mathrm{yt}}=0 \%$. I.e. there is no inheritance at all, no matter how large $\beta_{t}$ and $m_{t}$ might be. Conversely, in case people who die are on average twice as rich as the living ( $\mu_{\mathrm{t}}=200 \%$ ), then for $\beta_{\mathrm{t}}=600 \%$ and $\mathrm{m}_{\mathrm{t}}=2 \%$, the annual inheritance flow has to be equal to $24 \%$ of national income.

If we express the inheritance flow $B_{t}$ as a fraction of aggregate private wealth $W_{t}$, rather than as a fraction of national income $Y_{t}$, then the formula is even simpler:

$$
\begin{equation*}
b_{w t}=B_{t} / W_{t}=\mu_{t} m_{t} \tag{3.3}
\end{equation*}
$$

I.e. the inheritance-wealth ratio $b_{w t}$ is equal to the mortality rate multiplied by the $\mu_{\mathrm{t}}$ ratio. In case $\mu_{\mathrm{t}}=100 \%$, e.g. if the age-wealth profile is flat, then $b_{w t}$ is equal to the mortality rate. The estate multiplier $e_{t}=W_{t} / B_{t}$ is simply the inverse of $b_{w t}$. We will return to the evolution of the inheritance-wealth ratio $b_{w t}$ later in this paper. But for the most part we choose to focus the attention upon the inheritance-income ratio $b_{y t}$ and accounting equation (3.1), first because the evolution of the wealth-income ratio $\beta_{t}=W_{t} / Y_{t}$ involves economic processes that are interesting per se (and interact with the inheritance process); and next because national wealth data is missing in a number of countries, so that for future comparison purposes we find it useful to emphasize $b_{y t}$ ratios, which are easier to compute (if one has fiscal data). Also, $b_{y t}$ has arguably greater intuitive economic appeal than $b_{w t}$. E.g. it can easily be compared to other flow ratios such as the capital share $\alpha_{t}$ or the saving rate $s_{t}$.

An example with real numbers might be useful here. In 2008, per adult national income was about $35,000 €$ in France. Per adult private wealth was about $200,000 €$. That is, $\beta_{\mathrm{t}}=\mathrm{W}_{\mathrm{t}} / Y_{\mathrm{t}}=\mathrm{w}_{\mathrm{t}} / \mathrm{y}_{\mathrm{t}}=560 \%$. The mortality rate $\mathrm{m}_{\mathrm{t}}$ was equal to $1.2 \%$, and we estimate that $\mu_{\mathrm{t}}$ was approximately $220 \% .{ }^{21}$ It follows from equations (3.1) and (3.3) that the inheritance-

[^11]income ratio $b_{y t}$ was $14.7 \%$ and that the inheritance-wealth ratio $b_{y t}$ was $2.6 \%$. It also follows from equation (3.2) that average inheritance per decedent $b_{t}$ was about 440,000€, i.e. about 12.5 years of average income $y_{t}\left(\mu_{t} \times \beta_{t}=12.5\right)$. One can then introduce distributional issues: about half of decedents have virtually no wealth, the other half owns about twice the average (i.e. about 25 years of average income); and so on. ${ }^{22}$

For the time being, however, we concentrate on $b_{y t}$ and equation (3.1), which is more suitable for the macro level analysis of inheritance. But it is important to keep in mind that the three accounting equations (3.1), (3.2) and (3.3) are by construction fully equivalent.

What kind of data do we need in order to compute equation (3.1)? First, we need data on the wealth-income ratio $\beta_{\mathrm{t}}=\mathrm{W}_{\mathrm{t}} / Y_{\mathrm{t}}$. To a large extent, this is given by existing national accounts data, as described below. It is conceptually important to use private wealth as the numerator (i.e. the sum of all tangible and financial assets owned by private individuals, minus their financial liabilities) rather than national wealth (i.e. the sum of private wealth and government wealth). Private wealth can be transmitted at death, while government wealth cannot. Practically, however, this does not make a big difference, since private wealth usually represents over $90 \%$ of national wealth (i.e. government net wealth is typically positive but small). The choice of the income denominator is unimportant, as long as one uses the same denominator on both sides of the equation. For reasons explained in the introduction, we choose to use national income (rather for instance than personal disposable income) as the denominator.

Next, we need data on the mortality rate $\mathrm{m}_{\mathrm{t}}$. This is the easiest part: demographic data is plentiful and easily accessible. ${ }^{23}$ In practice, children usually own very little wealth and receive very little income. In order to abstract from the large historical variations in infant mortality, and in order to make the quantitative values of the $m_{t}$ and $\mu_{t}$ parameters easier to interpret, we define them over the adult population. That is, we define the mortality rate $m_{t}$ as the adult mortality rate, i.e. the ratio between the number of decedents aged 20-year-old and over and the number of living individuals aged 20-year-old and over.

[^12]Similarly, we define $\mu_{\mathrm{t}}$ as the ratio between the average wealth of decedents aged 20-year-old and over and the average wealth of living individuals aged 20-year-old and over. ${ }^{24}$

Finally, we need data to compute the $\mu_{\mathrm{t}}$ ratio. This is the most challenging part, and also the most interesting part from an economic viewpoint. In order to compute $\mu_{\mathrm{t}}$ we need two different kinds of data. First, we need data on the cross-sectional age-wealth profile. The more steeply rising the age-wealth profile, the higher the $\mu_{\mathrm{t}}$ ratio. Conversely, if the agewealth profile is strongly hump-shaped, then $\mu_{\mathrm{t}}$ will be smaller. Next, we need data on differential mortality. For a given age-wealth profile, the fact that the poor tend to have higher mortality rates than the rich implies a lower $\mu_{\mathrm{t}}$ ratio. In the extreme case where only the poor (say, zero-wealth individuals) die, and the rich never die, then the $\mu_{\mathrm{t}}$ ratio will be permanently equal to $0 \%$ (even with a steeply rising cross-sectional age-wealth profile), and there will be no inheritance. There exists a large research literature on differential mortality. We simply borrow the best available estimates from this literature. We checked that these differential mortality factors are consistent with the age-at-death differential between wealthy decedents and poor decedents, as measured by estate tax data and demographic data; they are consistent. ${ }^{25}$

Regarding the age-wealth profile, one would ideally like to use exhaustive, administrative data on the wealth of the living, such as wealth tax data. However such data generally does not exist for long time periods, and/or only covers relatively small segments of the population. Wealth surveys do cover the entire population, but they are not fully reliable (especially for top wealth holders, which might bias estimated age-wealth profiles), and in any case they are not available for long time periods. The only data source offering longrun, reliable raw data on age-wealth profiles appears to be the estate tax itself. ${ }^{26}$ This is wealth-at-death data, so one needs to use the differential mortality factors to convert them back into wealth-of-the-living age-wealth profiles. ${ }^{27}$ This data source combines many advantages: it covers the entire population (nearly everybody has to file an estate tax

[^13]return in France), and it is available on a continuous and homogenous basis since the beginning of the $19^{\text {th }}$ century. We checked that the resulting age-wealth profiles are consistent with those obtained with wealth tax data and (corrected) wealth survey data for the recent period (1990s-2000s); they are consistent. ${ }^{28}$

We have now described how we proceed in order to compute our "economic inheritance flow" series using equation (3.1). There is however one important term that needs to be added to the computation in order to obtain meaningful results. In the real world, inter vivos gifts do exist and play an important role in the process of intergenerational wealth transmission and in shaping the age-wealth profile. In France, gifts have always represented a large fraction of total wealth transmission (around 20\%-30\%), and moreover this fraction has changed a lot over time (currently it is almost 50\%). Not taking them into account would bias the results in important ways. The simplest way to take gifts into account is to correct equation (3.1) in the following way:

$$
\begin{equation*}
B_{t} / Y_{t}=\mu_{t}^{*} m_{t} W_{t} / Y_{t} \tag{3.1’}
\end{equation*}
$$

With: $\mu_{\mathrm{t}}{ }^{*}=\left(1+\mathrm{v}_{\mathrm{t}}\right) \mu_{\mathrm{t}}=$ gift-corrected ratio between decedents wealth and wealth of the living $\mathrm{V}_{\mathrm{t}}=\mathrm{V}_{\mathrm{t}}^{\mathrm{f} 0} / \mathrm{B}_{\mathrm{t}}^{\text {f0 }}=$ observed fiscal gift-bequest ratio
$B_{t}{ }^{\text {f0 }}=$ raw fiscal bequest flow (total value of bequests left by decedents during year $t$ )
$V_{t}^{\text {f0 }}=$ raw fiscal gift flow (total value of inter vivos gifts made during year $t$ )

Equation (3.1') simply uses the observed, fiscal gift-bequest ratio during year t and upgrades the economic inheritance flow accordingly. Intuitively, the gift-corrected ratio $\mu_{\mathrm{t}}{ }^{*}$ attempts to correct for the fact that the raw $\mu_{t}$ under-estimates the true relative importance of decedents' wealth (decedents have already given away part of their wealth before they die, so that their wealth-at-death looks artificially low), and attempts to compute what the $\mu_{t}$ ratio would have been in the absence of inter-vivos gifts. Of course, this simple way to proceed is not fully satisfactory, since the individuals who make gifts during year $t$ are usually not the same as the individuals who die during year $t$ (on average gifts are made about 7-8 years before the time of death). In the simulated model, we re-attribute gifts to the proper generation of decedents, and re-simulate the entire age-wealth profile dynamics in the absence of gifts. We show that this creates time lags, but does not significantly affect long-run levels and patterns of the inheritance-income ratio.

[^14]Before we present and analyse the results of these computations, we give more details about our two main data sources: national accounts data and estate tax data. Readers who feel uninterested by these details might want to go directly to section 4.

### 3.2. National income and wealth accounts: $Y_{t}$ and $W_{t}$

National income and wealth accounts have a long tradition in France, and available historical series are of reasonably high quality. ${ }^{29}$ In particular, the national statistical institute (Insee) has been compiling official national accounts series since 1949. Homogenous, updated national income accounts series covering the entire 1949-2008 period and following the latest international guidelines were recently released by Insee. These are the series we use in this paper for the post-1949 period, with no adjustment whatsoever. National income $Y_{t}$ and its components are defined according to the standard international definitions: national income equals gross domestic product minus capital depreciation plus net foreign factor income, etc.

Prior to 1949, there exists no official national accounts series in France. However a very complete set of retrospective, annual income accounts series covering the 1896-1949 period was compiled and published by Villa (1994). These series use the concepts of modern national accounts and are based upon a systematic comparison of raw output, expenditure and income series constructed by many authors. Villa also made new computations based upon raw statistical material. Although some of year-to-year variations in this data base are probably fragile, there are good reasons to view these annual series as globally reliable. ${ }^{30}$ These are the series we use for the 1896-1949 period, with minor adjustments, so as to ensure continuity in 1949. Regarding the 1820-1900 period, though a number of authors have produced annual national income series, we are not sure that the limited raw statistical material available for the $19^{\text {th }}$ century makes such an exercise really meaningful. Moreover we do not really need annual series for our purposes. So for the $19^{\text {th }}$ century, we use decennial-averages estimates of national income (these

[^15]decennial averages are almost identical across the different authors and data sources), and we assume fixed growth rates, saving rates and factor shares within each decade. ${ }^{31}$

The national wealth part of our macro data base requires more care than the national income part. It is only in 1970 that Insee started producing official, annual national wealth estimates in addition to the standard national income estimates. For the post-1970 period, the wealth and income sides of French national accounts are fully integrated and consistent. That is, the balance sheets of the personal sector, the government sector, the corporate sector, and the rest of the world, estimated at asset market prices on January $1^{\text {st }}$ of each year, are fully consistent with the corresponding balance sheets estimated on the previous January $1^{\text {st }}$ and the income and savings accounts of each sector during the previous year, and the recorded changes in asset prices. ${ }^{32}$ We use these official Insee balance sheets for the 1970-2009 period, with no adjustment whatsoever. We define private wealth $W_{t}$ as the net wealth (tangible assets, in particular real estate, plus financial assets, minus financial liabilities) of the personal sector. $W_{t}$ is estimated at current asset market prices (real estate assets are estimated at current real estate prices, equity assets are estimated at current stock market prices, etc.). This is exactly what we want, since our objective is to relate aggregate private wealth to the inheritance flow, and since according to estate tax law - the value of bequests is always estimated at the market prices of the day of death (or on the day the gift is made). Although this is of no use for our purposes, one can also define government wealth $\mathrm{W}_{\mathrm{gt}}$ as the net wealth of the government sector, and national wealth $\mathrm{W}_{\mathrm{nt}}=\mathrm{W}_{\mathrm{t}}+\mathrm{W}_{\mathrm{gt}}$. According to the Insee estimates, private wealth during the 1990 s-2000s has always represented around $90 \%-95 \%$ of national wealth. I.e. government wealth is positive but small: government tangible and financial assets only slightly exceed the value of government debt. During the 1970s-1980s, private wealth was equal to about $85 \%-90 \%$ of national wealth. Government net wealth was somewhat bigger than it is today, both because public debt was smaller and because the government owned more tangible and financial assets (the public sector was bigger at that time). ${ }^{33}$

Prior to 1970, we have to use various non-official, national wealth estimates. For the 18201913 period, national wealth estimates are plentiful and relatively reliable. This was a time of almost zero inflation ( $0.5 \%$ per year on average during the 1820-1913 period), so there

[^16]was no big problem with asset prices. Most importantly, the economists of the time were literally obsessed with national wealth (which they found to be much more interesting than national income), and many of them produced relatively sophisticated national wealth estimates. They used the decennial censuses of tangible assets organized by the tax administration (the tax system of the time relied extensively on the property values of real estate, land and business assets, so such censuses played a critical role). They took into account the growing stock and bond market capitalisation and the booming foreign assets, and they explained in a precise and careful manner how they made all the necessary corrections in order to avoid all forms of double counting. We certainly do not pretend that these national wealth estimates are perfectly comparable to the modern, official balance sheets. In particular, these estimates are never available on an annual basis, and they certainly cannot be used to do short run business cycle analysis. But as far as decennial averages are concerned, we consider that the margin of error on these estimates does not exceed $5 \%-10 \%$. As compared to the enormous historical variations in aggregate wealthincome ratios and in the inheritance-income ratio, in which we are primarily interested in, such margins of errors are negligible. According to these national wealth estimates, private wealth at that time accounted for as much as $97 \%-98 \%$ of national wealth, i.e. net government wealth was slightly positive but negligible.

The period 1914-1969 is the time period for which French national wealth estimates are the most problematic. This was a chaotic time for wealth, both because of war destructions and because of large inflation and wide variations in the relative price of the various assets. Very few economists compiled detailed, reliable national balance sheets for this time period. We proceed as follows. We use only two data points, namely the national wealth estimate for year 1925 due to Colson (1927), and the national wealth estimate for year 1954 due to Divisia, Dupin and Roy (1956). These are the two most sophisticated estimates available for this time period. They both rely on a direct wealth census method, and they both attempt to estimate assets and liabilities at asset market prices prevailing in 1925 and 1954, which is what we want. Moreover, Colson is the author of some of the most sophisticated pre-World War 1 national wealth estimates (we used his estimates for 1896 and 1913), and his 1925 computations are based on the same methods and sources as those used for 1896 and 1913. Divisia and his co-authors view the Colson 1896-19131925 estimates as their model, and they also attempt to follow the same methodology. To the extent that national wealth can be estimated during such a chaotic time period, this is probably the best one can find.

For the missing years, we estimate private wealth $W_{t}$ by using a simple wealth accumulation equation, based upon the private saving flows $S_{t}$ coming from national income accounts. Generally speaking, year-to-year variations in private wealth $W_{t}$ can be due either to volume effects (savings) or to price effects (asset prices might rise or fall relatively to consumer prices). That is, the accumulation equation for private wealth can be written as follows:

$$
\begin{equation*}
W_{t+1}=\left(1+q_{t+1}\right)\left(1+p_{t+1}\right)\left(W_{t}+S_{t}\right) \tag{3.4}
\end{equation*}
$$

In equation (3.4), $\mathrm{p}_{\mathrm{t}+1}$ is consumer price inflation between year t and year $\mathrm{t}+1$, and $\mathrm{q}_{\mathrm{t}+1}$ is the real rate of capital gain (or capital loss) between year $t$ and year $t+1$, which we define as the excess of asset price inflation over consumer price inflation. For the 1970-2009 period, since French national income and wealth accounts are fully integrated, $q_{t}$ can indeed be interpreted as the real rate of capital gains. For the pre-1970 period, $\mathrm{q}_{\mathrm{t}}$ is better interpreted as a residual error term: it includes real asset price inflation, but it also includes all the variations in private wealth that cannot be accounted for by saving flows. For simplicity, we assume a fixed $q_{t}$ factor during the 1954-1970 period (i.e. we compute the implicit average $\mathrm{q}_{\mathrm{t}}$ factor needed to account for 1970 private wealth, given 1954 private wealth and 1954-1969 private savings flows). We do the same for the 1925-1954 period, the 1913-1925 period, and for each decade of the 1820-1913 period. The resulting decennial averages for the private wealth-national income ratio $\beta_{t}=W_{t} / Y_{t}$ are plotted on Figure 4. Summary statistics on the accumulation of private wealth in France over the entire 1820-2009 period are given on Table 1.

Again, we do not pretend that the resulting annual series are fully satisfactory, and we certainly do not recommend that one uses them for short run business cycle analysis, especially for the 1913-1925 and 1925-1954 sub-periods, for which the simplifying assumption of a fixed capital gain effect makes little sense. However we believe that the resulting decennial averages are relatively precise. In particular, it is re-insuring to see that most of wealth accumulation in the medium and long run seems to be well accounted for by savings. This suggests that saving rates are reasonably well measured by our national accounts series, and that in the long run there exists no major divergence between asset prices and consumer prices. The fact that our private wealth series delivers economic
inheritance flow estimates that are reasonably well in line with the observed fiscal flow also gives us confidence about our wealth estimates.

A few additional points about the long-run evolution of the wealth-income ratio $\beta_{\mathrm{t}}$ might be worth noting here. ${ }^{34}$ Consider first the 1820-1913 period. We find that $\beta_{\mathrm{t}}$ gradually rose from about $550 \%-600 \%$ around 1820 to about $650 \%-700 \%$ around 1900-1910 (see Figure 4). The real growth rate $g$ of national income was $1.0 \% .^{35}$ The savings rate s was about $8 \%-9 \%$, so that the average savings-induced wealth growth rate $g_{w s}=s / \beta$ was $1.4 \%$. I.e. it was larger than $g$. This explains why the wealth-income ratio was rising during the $19^{\text {th }}$ century: savings were slightly higher than the level required for a steady-state growth path (i.e. the savings rate was slightly higher than $s^{*}=\beta g=6 \%-7 \%$ ). The observed real growth rate of private wealth $g_{w}$ was actually $1.3 \%$, i.e. slightly below $g_{w s}$. In our accounting framework, we attribute the differential to changes in the relative price of assets, and we find a modest negative q effect ( $-0.1 \%$ ) (see Table 1). Of course, it could just be that we slightly overestimate $19^{\text {th }}$ century saving rates, or that we slightly underestimate the $19^{\text {th }}$ century rise in the wealth-income ratio, or both. But the important point is that our stock and flow series are broadly consistent. Although the data is imperfect, it is also well established that a very substantial fraction of the $19^{\text {th }}$ century rise in the wealth-income ratio (and possibly all of it) went though the accumulation of large foreign assets. ${ }^{36}$

Consider now the 1913-2009 period. The real growth rate g of national income was $2.6 \%$, thanks to the high growth postwar decades. The real growth rate of private wealth $\mathrm{g}_{\mathrm{w}}$ was $2.4 \%$. Given observed saving flows (and taking into account wartime capital destructions, which we include in volume effects), private wealth should have grown slightly faster, i.e. we find that the saving-induced wealth growth rate $g_{w s}$ was $2.9 \%$. We again attribute the differential to real capital gains, and we find a modest negative q effect ( $-0.4 \%$ ) (see Table 1). Taken literally, this would mean that the 1949-2009 gradual rise in the relative price of assets has not yet fully compensated the 1913-1949 fall, and that asset prices are currently about $30 \%$ lower than what they were at the eve of World War 1. Again, it could also be that we slightly overestimate $20^{\text {th }}$ century saving flows, or underestimate end-of-

[^17]period wealth stocks. ${ }^{37}$ The important point is that our stock and flow data sources are mutually consistent. In the long run, the bulk of wealth accumulation is well accounted for by savings, both during the $19^{\text {th }}$ and the $20^{\text {th }}$ century. As a first approximation, the 19131949 fall in the relative price of assets seems to have been almost exactly compensated by the 1949-2009 rise, so that the total 1913-2009 net effect is close to zero.

The other important finding is that the 1913-1949 fall in the aggregate wealth-income ratio was not due - for the most part - to the physical destructions of the capital stock that took place during the wars. We find that $\beta_{\mathrm{t}}$ dropped from about $600 \%-650 \%$ in 1913 to about $200 \%-250 \%$ in 1949. Physical capital destructions per se seem to account for little more than $10 \%$ of the total fall. On the basis of physical destructions and the observed saving response (saving flows were fairly large in the 1920s and late 1940s), we find that private wealth should have grown at $\mathrm{g}_{\mathrm{ws}}=0.9 \%$ per year between 1913 and 1949, i.e. almost as fast as national income ( $\mathrm{g}=1.3 \%$ ). However the market value of private wealth fell dramatically $\left(g_{w}=-1.7 \%\right)$, which we attribute to a large negative $q$ effect ( $q=-2.6 \%$ ). This large real rate of capital loss can be broken down into a variety of factors: holders of nominal assets (public and private bonds, domestic and foreign) were literally expropriated by inflation; real estate prices fell sharply relatively to consumer prices (probably largely due to sharp rent control policies enacted in the 1920s and late 1940s); and stock prices also fell to historical lows in 1945 (probably reflecting the dramatic loss of faith in capital markets, as well as the large nationalization policies and capital taxes enacted in the aftermath of World War 2). In effect, the 1914-1945 political and military shocks generated an unprecedented wave of anti-capital policies, which had a much larger impact on private wealth than the wars themselves.

This asset price effect explains why the wealth-income ratio also seems to have fallen substantially in countries whose territories were not directly hit by the wars. In the U.K., the private wealth-national income ratio was apparently as large as $650 \%-750 \%$ in the late $19^{\text {th }}$ and early $20^{\text {th }}$ century, down to $350 \%-400 \%$ in the 1950 s-1970s, up to about $450 \%$ -

[^18]$550 \%$ in the 1990 s-2000s. ${ }^{38}$ In the U.S., it seems to have declined from about 550\%-600\% in the early $20^{\text {th }}$ century and in the interwar period to about $350 \%-400 \%$ in the 1950 s1970s, up to $450 \%-500 \%$ in the 1990s-2000s. ${ }^{39}$ This suggests that the U.K. and the U.S. have gone through the same U-shaped pattern as France - albeit in a somewhat less pronounced manner, which seems consistent with the above observations. We stress however that these U.K.-U.S. series are not fully homogenous over time; nor are they fully comparable to our French series. We report them for illustrative purposes only. The Ushaped pattern is probably robust, but the exact levels should be interpreted with caution.

Finally, it is worth noting that if we use disposable income rather than national income as the denominator, then the wealth-income ratios reached in France in the 2000s (750\%$800 \%$ ) appear to be slightly higher than the levels observed in the $19^{\text {th }}$ and early $20^{\text {th }}$ century, rather than slightly smaller (see Figure 5). We feel that it is more justified to look at the wealth-national income ratios, but this is a matter of perspective.

### 3.3. Estate tax data: $B_{t}{ }^{f}, \mu_{t}$ and $v_{t}$

Estate tax data is the other key data source used in this paper. ${ }^{40}$ It plays an essential role for several reasons. First, because of various data imperfections (e.g. regarding national wealth estimates), we thought that it was important to compute two independent measures of inheritance flows: one "economic flow" indirect measure (based upon national wealth estimates and mortality tables, as described above) and one "fiscal flow" direct measure. The fiscal flow is a direct measure in the sense that it was obtained simply by dividing the observed aggregate bequest and gift flow reported to the tax administration (with a few corrections, see below) by national income, and therefore makes no use at all of national wealth estimates. Next, we need estate tax data in order to compute the gift-bequest ratio $\mathrm{V}_{\mathrm{t}}=\mathrm{V}_{\mathrm{t}}^{\mathrm{f0}} / \mathrm{B}_{\mathrm{t}}^{\mathrm{f0}}$, and in order to obtain reliable, long-run data on the age-wealth profile and to

[^19]compute the $\mu_{\mathrm{t}}$ ratio. Finally, we also use estate tax data in order to know the age structure of decedents, heirs, donors and donees, which we need for our simulations.

French estate tax data is exceptionally good, for one simple reason. As early as 1791, shortly after the abolition of the tax privileges of the aristocracy, the French National Assembly introduced a universal estate tax, which has remained in force since then. This estate tax was universal because it applied both to bequests and to inter-vivos gifts, at any level of wealth, and for nearly all types of property (both tangible and financial assets). The key characteristic of the tax is that the successors of all decedents with positive wealth, as well as all donees receiving a positive gift, have always been required to file a return, no matter how small the estate was, and no matter whether the heirs and donees actually ended up paying a tax or not. This followed from the fact that the tax was thought more as a registration duty than as a tax: filling a return has always been the way to register the fact that a given property has changed hands and to secure one's property rights. ${ }^{41}$

Between 1791 and 1901, the estate tax was strictly proportional. The tax rate did vary with the identity of the heir or donee (children and surviving spouses have always faced much lower tax rates than other successors in the French system), but not with the wealth level. The proportional tax rates were fairly small (generally $1 \%-2 \%$ for children and spouses), so there was really very little incentive to cheat. The estate tax was made progressive in 1901. In the 1920s, tax rates were sharply increased for large estates. In 1901, the top marginal rate applying to children heirs was as small as $5 \%$; by the mid 1930s it was $35 \%$; it is currently $40 \%$. Throughout the $20^{\text {th }}$ century these high top rates were only applied to small segments of the population and assets. So the aggregate effective tax rate on estates has actually been relatively stable around $5 \%$ over the past century in France. ${ }^{42}$ Most importantly, the introduction of tax progressivity did not significantly affect the universal legal requirement to fill a return, no matters how small the bequest or gift.

There is ample evidence that this legal requirement has been applied relatively strictly, both before and after the 1901 reform. In particular, the number of estate tax returns filled

[^20]each year has generally been around $65 \%$ of the total number of adult decedents (about 350,000 yearly returns for 500,000 adult decedents, both in the 1900s and in the 2000s). This is a very large number, given that the bottom $50 \%$ of the population hardly owns any wealth at all. We do upgrade the raw fiscal flow in order to take non-filers into account, but the point is that the corresponding correction is small (generally around 5\%-10\%).

The other good news for scholars is that the raw tax material has been well archived. Since the beginning of the $19^{\text {th }}$ century, the tax authorities transcribed individual returns in registers that have been preserved. In a previous paper we used these registers to collect large micro samples of Paris decedents every five year between 1807 and 1902, which allowed us to study the changing concentration of wealth and the evolution of age-wealth profiles. ${ }^{43}$ Ideally one would like to collect micro samples for the whole of France over the two-century period, but this has proved to be too costly so far.

So in this paper we rely mostly on aggregate national data collected by the tax administration. For the 1826-1964 period, we use the estate tax tabulations published on a quasi-annual basis by the French Ministry of Finance. For the whole period, these tables indicate the aggregate value of bequests and gifts reported in estate tax returns, which is the basic information that we need. Starting in 1902, these annual publications also include detailed tabulations on the number and value of bequests and gifts broken down by size of estate and age of decedent or donor. These tabulations were abandoned in the 1960s-1970s, when the tax administration started compiling electronic files with nationally representative samples of bequest and gift tax returns. We use these so-called "DMTG" micro files for years 1977, 1984, 1987, 1994, 2000 and 2006. The data is not annual, but it is very detailed. Each micro-file includes all variables reported in tax returns, including the value of the various types of assets, total estate value, the share going each heir or donee, and the demographic characteristics of decedents, heirs, donors and donees.

We proceed as follows. We start from the raw fiscal bequest flow $B_{t}{ }^{\text {f0 }}$, i.e. the aggregate net wealth transmitted at death, as reported to tax authorities by heirs, whoever they are. In particular, we do not exclude the estate share going to surviving spouses, first because it has always been relatively small (about 10\%), ${ }^{44}$ and next because we choose in the

[^21]present paper to adopt a gender-free, individual-centred approach to inheritance. So we ignore marriage and gender issues altogether, which given our aggregate perspective seems to be the most appropriate option. ${ }^{45}$

We first make an upward correction to $\mathrm{B}_{\mathrm{t}}{ }^{\text {f0 }}$ for non filers (see above), and we then make another upward correction for tax exempt assets. When the estate tax was first created, the major exception to the universal tax base was government bonds, which benefited from a general estate tax exemption until 1850. Between 1850 and World War 1, very few assets were exempted (except fairly specific assets like forests). Shortly after World War 1, and again after World War 2, temporary exemptions were introduced for particular types of government bonds. In order to foster reconstruction, new real estate property built between 1947 and 1973 also benefited from a temporary exemption. Most importantly, a general exemption for life insurance assets was introduced in 1930. It became very popular in recent decades. Life insurances assets were about $2 \%$ of aggregate wealth in the 1970s and grew to about $15 \%$ in the 2000s. Using various sources, we estimate that the total fraction of tax exempt assets in aggregate private wealth gradually rose from less than $10 \%$ around 1900 to $20 \%$ in the interwar period, $20 \%-25 \%$ in the 1950 s-1970s and $30 \%-35 \%$ in the 1990s-2000s. We upgrade the raw fiscal bequest flow accordingly.

We apply the same upward corrections to inter vivos gifts, leaving the gift-bequest ratio $v_{t}$ unaffected. To the extent that gifts are less well reported to tax authorities than bequests, this implies that we probably under-estimate their true economic importance. Also, in this paper we entirely ignore informal monetary and in-kind transfers between households, as well as parental transfers to children taking the form of educational investments, tuition fees and other non-taxable gifts (which ideally should all be included in the analysis, in one way or another). ${ }^{46}$ That is, we only consider formal, potentially taxable gifts.

[^22]
## 4. The U-shaped pattern of inheritance: a simple decomposition

The accounting equation $B_{t} / Y_{t}=\mu_{t}^{*} m_{t} W_{t} / Y_{t}$ allows for a simple and transparent decomposition of changes in the aggregate inheritance flow. Here the important finding is that the long-run $U$-shaped pattern of $B_{t} / Y_{t}$ is the product of three $U$-shaped curves, which explains why it was so pronounced. We take these three effects in turn: the aggregate wealth-income effect $W_{t} / Y_{t}$, the mortality rate effect $m_{t}$, and the $\mu_{t}{ }^{*}$ ratio effect.

### 4.1. The aggregate wealth-income ratio effect $W_{t} / \underline{Y}_{t}$

We already described the U-shaped pattern the aggregate wealth-income ratio $\beta_{t}$ (see Figure 4). By comparing this pattern with that of the inheritance flow byt (see Figure 2), one can see that the 1913-1949 decline in the aggregate wealth-income ratio explains about half of the decline in the inheritance-income ratio. Between 1913 and 1949, $\beta_{\mathrm{t}}$ dropped from $650 \%-700 \%$ to $200 \%-250 \%$. I.e. it was divided by a factor of about 2.5-3. In the meantime, $b_{y t}$ dropped from $20 \%-25 \%$ to $4 \%$. l.e. it was divided by a factor of about 5-6.

### 4.2. The mortality rate effect $\mathrm{m}_{\mathrm{t}}$

Where does the other half of the decline in the inheritance-income ratio come from? By construction, it comes from a combination of $\mu_{t}{ }^{*}$ and $m_{t}$ effects. The simplest term to analyze is the mortality rate $\mathrm{m}_{\mathrm{t}}$. The demographic history of France since 1820 is simple. Population was growing at a small rate during the $19^{\text {th }}$ century (less than $0.5 \%$ per year), and was quasi-stationary around 1900 ( $0.1 \%$ ). The only time of sustained population growth during the past two centuries was due to the well-known postwar baby-boom, with population growth rates around $1 \%$ in the 1950s-1960s. Population growth has been declining since then, and in the 1990s-2000s it was approximately $0.5 \%$ per year (about a third of which comes from net migration flows). According to official projections, population growth will be less than $0.1 \%$ by 2040-2050, with a quasi-stationary population after 2050. Adult population was about 20 millions in the 1820s, 30 millions in the 1950s, 50 millions in the 2010s, and is projected to stabilize below 60 millions.

The evolution of mortality rates follows directly from this and from the evolution of life expectancy. Between 1820 and 1910, the mortality rate was relatively stable around $2.2 \%-$ $2.3 \%$ per year (see Figure 6). This corresponds to the fact that the population was growing
at a very small rate, and that life expectancy was stable around 60, with a slight upward trend (see Figure 7). In a world with a fully stationary population and a fixed adult life expectancy equal to 60, then the adult mortality rate (i.e. the mortality rate for individuals aged 20 -year-old and above) should indeed be exactly equal to $1 / 40=2.5 \%$. Since population was rising a little bit, the mortality rate was a bit below that.

There was a purely temporary rise in mortality rates in the 1910s and 1940s due to the wars. Ignoring this, we have a regular downward trend in the mortality rate during the $20^{\text {th }}$ century, with a decline from about $2.2 \%-2.3 \%$ in 1910 to about $1.6 \%$ in the 1950s-1960s and $1.1 \%-1.2 \%$ in the 2000 s. According to official projections, this downward trend is now over, and the mortality rate is bound to rise in the coming decades, and to stabilize around $1.4 \%-1.5 \%$ after 2050 (see Figure 6). This corresponds to the fact that the French population is expected to stabilize by 2050 , with an age expectancy of about 85 , which implies a stationary mortality rate equal to $1 / 65=1.5 \%$. The reason why the mortality rate is currently much below this steady-state level is because the large baby-boom cohorts are not dead yet. When they die, i.e. around 2020-2030, then the mortality rate will mechanically increase, and so will the inheritance flow. This simple demographic arithmetic is obvious, but important. In the coming decades, this is likely to be a very big effect in countries with negative projected population growth (Spain, Italy, Germany). In the extreme case where each couple has only one kid, the new cohorts are twice as small as the dying cohorts, and inheritance flows can mechanically become very large.

However the large inheritance flows observed in the 2000s are not due to a mortally rate effect. The U-shaped mortality effect will start operating only in future decades. The 20002010 period actually corresponds to the lowest historical mortality ever observed, with mortality rates as low as $1.1 \%-1.2 \%$. On the basis of mortality rates alone, the inheritance flow in the 1990s-2000s should have been much smaller than what we actually observe.

### 4.3. The $\mu_{t}^{*}$ ratio effect

So why has there been such a strong recovery in the inheritance flow since the 1950s1960s, and why is the inheritance flow so large in the 1990s-2000s? We now come to the most interesting part, namely the $\mu_{\mathrm{t}}{ }^{*}$ ratio effect. Here it is important to distinguish between the raw ratio $\mu_{\mathrm{t}}$ and the gift-corrected ratio $\mu_{\mathrm{t}}^{*}=\left(1+\mathrm{v}_{\mathrm{t}}\right) \mu_{\mathrm{t}}$. We plot on Figure 8 the historical evolution of the $\mu_{\mathrm{t}}$ and $\mu_{\mathrm{t}}{ }^{*}$ ratios, as estimated using observed age-wealth-at-death profiles
and differential mortality parameters. We plot on Figure 9 the inheritance flow-private wealth ratio $b_{w t}=m_{t} \mu_{t}{ }^{*}$. We also show on Table 2 some of the raw wealth-at-death profiles that we used for the computation of our $\mu_{\mathrm{t}}$ series.

Between 1820 and 1910, the $\mu_{\mathrm{t}}$ ratio was around $130 \%$. I.e. on average decedents' wealth was about $30 \%$ bigger than the average wealth of the living. There was actually a slight upward trend, from about $120 \%$ in the 1820s to about $130 \%-140 \%$ in 1900-1910. But this upward trend disappears once one takes inter vivos gifts into account: the gift-bequest ratio $v_{t}$ was as high as $30 \%-40 \%$ during the 1820s-1850s, and then gradually declined, before stabilizing at about $20 \%$ between the 1870 s and 1900-1910. ${ }^{47}$ When we add this gift effect, i.e. when we take into account the fact that decedents have already given away about $30 \%-40 \%$ of their wealth when they die in the 1820 s-1840s, and about $20 \%$ of their wealth when they die in the 1870s-1910s, then we find that the gift-corrected $\mu_{\mathrm{t}}{ }^{*}$ ratio was stable at about 160\% during the 1820-1913 period (see Figure 8).

During this entire period, cross-sectional age-wealth profiles were steeply increasing up until the very old, and were becoming more and more steeply increasing over time (see Table 2). ${ }^{48}$ Here we report and use profiles for the all of France. In Paris, where many of the top wealth holders lived, age-wealth profiles were even more steeply increasing. ${ }^{49}$

The 1913-1949 capital shocks clearly had a strong disturbing impact on age-wealth profiles. Observed profiles gradually become less and less steeply-increasing at old age after World War 1, and shortly become hump-shaped in the aftermath of World War 2 (see Table 2). ${ }^{50}$ Consequently, our $\mu_{\mathrm{t}}$ ratio estimates declined from about $140 \%$ at the eve of World War 1 to about $90 \%$ in the 1940s (see Figure 8). The gift-bequest ratio was stable around $20 \%$ throughout this period, so the $\mu_{t}{ }^{*}$ went through a similar evolution.

One possible explanation for this change in pattern is that it was too late for the elderly to recover from the capital shocks (war destruction, capital losses), while active and younger

[^23]cohorts could earn labour income and accumulate new wealth. It could also be that elderly wealth holders were hit by proportionally larger shocks, e.g. because they held a larger fraction of their assets in nominal assets such as public bonds.

The most interesting fact is the strong recovery of the $\mu_{t}$ and $\mu_{t}{ }^{*}$ ratios which took place since the 1950s. The raw age-wealth-at-death profiles gradually became upward sloping again. In the 1900 s-2000s, decedents aged 70 and over are about $20 \%-30 \%$ richer than the 50-to-59-year-old decedents (see Table 2). ${ }^{51}$ As a consequence, the $\mu_{\mathrm{t}}$ ratio gradually rose from about $90 \%$ in the 1940s-1950s to over $120 \%$ in the 2000s (see Figure 8).

Next, and most importantly, the gift-bequest ratio $\mathrm{v}_{\mathrm{t}}$ rose enormously since the 1950 s . The gift-bequest ratio was about $20 \%-30 \%$ in the 1950 s-1960s, and then gradually increased to about $40 \%$ in the 1980 s, $60 \%$ in the 1990s and over $80 \%$ in the 2000 s. This is by far the highest historical level ever observed. Gifts currently represent almost $50 \%$ of total wealth transmission (bequests plus gifts) in France. That is, when we observe wealth at death, or wealth among the elderly, we are actually observing the wealth of individuals who have already given away almost half of their wealth. So it would make little sense to study agewealth profiles without taking gifts into account. Gifts are probably less well reported than bequests to the tax administration, so it is hard to see how our tax-data-measured $v_{t}$ ratio can be over-estimated. If anything, we probably underestimate the gift effect. We do not know whether such as large rise in gifts also occurred in other countries. ${ }^{52}$

The age differential between decedents and donors has remained relatively stable around $7-8$ years throughout the $20^{\text {th }}$ century, and in particular during the past few decades. On average, people have always made gifts about 7-8 years before they die. So the impact of gifts on the average age at which individuals receive wealth transfers has been relatively limited. We compute the evolution of the average age of "receivers" (by weighting average age of heirs and average age of donees by the relevant amounts), and we find that the rise

[^24]of gifts since the 1980s merely led to a pause in the historical rise in the average age of receivers (currently about 45-year-old), but not to an absolute decline. ${ }^{53}$

The most plausible interpretation for this large increase in gifts is the rise in life expectancy: wealthy parents realize that they are not going to die very soon, and decide that they should help their children to buy an apartment or start a business before they die. Tax incentives might also have played a role. ${ }^{54}$ There is an issue as to whether such a high gift-bequest ratio is sustainable in the long run, which we address in the simulations.

For the time being, it is legitimate to add the gift flow to the bequest flow, especially given the relatively small and stable age differential between decedents and donors. Consequently, we find that the gift-corrected $\mu_{t}{ }^{*}$ ratio has increased enormously since World War 2, from about $120 \%$ in the 1940s-1950s to over $180 \%$ in the 1990 s and over $220 \%$ in the 2000s (see Figure 8).

To summarize: the long run decline in the mortality $\mathrm{m}_{\mathrm{t}}$ seems to have been (partially) compensated by a long run increase in the $\mu_{t}{ }^{*}$ ratio. Consequently, the product of two, i.e. the inheritance-wealth ratio $b_{w t}=m_{t} \mu_{t}^{*}$, declined much less than the mortality rate: $b_{w t}$ was about $3.3 \%-3.5 \%$ in the $19^{\text {th }}$ century (the estate multiplier $\mathrm{e}_{\mathrm{t}}=1 / \mathrm{b}_{\mathrm{wt}}$ was about 30 ), and it is above $2.5 \%$ in the 2000s (the estate multiplier is about 40). One obvious explanation as to why wealth tends to get older when age expectancy increases is because individuals wait longer before they inherit. However there are many other effects going on, so it is useful to clarify this simple effect with a stylized model, before moving on to full-fledged simulations.

[^25]
## 5. Wealth accumulation, inheritance \& growth: a simple steady-state model

Why is it that the long-run decline in mortality rate $\mathrm{m}_{\mathrm{t}}$ seems to be compensated by a corresponding increase in the $\mu_{\mathrm{t}}$ ratio? I.e. why does the relative wealth of the old seem to rise with life expectancy? More generally, what are the economic forces that seem to be pushing for a constant inheritance-income steady-state ratio byt (around 20\% of national income), independently from life expectancy and other parameters?

In order to highlight the key effects at play, we develop in this section a stylized theoretical model of wealth accumulation, inheritance and growth. We use various savings models (exogenous savings model, dynastic model, and wealth-in-the-utility model) and derive simple steady-state formulas for the $\mu_{\mathrm{t}}$ ratio and the inheritance-income and inheritancewealth ratios $b_{y t}=\mu_{t} m_{t} \beta_{t}$ and $b_{w t}=\mu_{t} m_{t}$. We prove two main results.

First, we show that with pure class savings, then the $m_{t}$ and $\mu_{t}$ effects exactly compensate one another, so that the steady-state ratios $b_{w t}$ and $b_{y t}$ are simply equal to $1 / \mathrm{H}$ and $\beta / H$, where H is generation length (age at parenthood) and $\beta$ is the aggregate wealth income ratio. That is, inheritance ratios do not depend at all on life expectancy or the growth rate.

Next, we show that this result extends to other saving models, assuming that growth rates are relatively low. Typically, for $\mathrm{g}=1 \%$ or $\mathrm{g}=2 \%$, inheritance ratios are almost exclusively determined by the age at parenthood H - and not so much on life expectancy and other parameters (thereby providing an explanation for the $20 \%$ magic number). More generally, we find that the steady-state ratios $\mu, b_{y}$ and $b_{w}$ always tend to be decreasing functions of the growth rate $g$ and increasing functions of the rate of return $r$. That is, higher growth and/or lower rates of return reduce the relative importance of inheritance.

The steady-state inheritance formulas developed in this section are simple and can be used with real numbers so as to better understand the quantitative importance of each effect. However they naturally rely on strong demographic and macroeconomic steadystate assumptions, which are at odds with the real world. In section 6, we present simulation results based upon a full-fledged, out-of-steady-state version of this model, using observed demographic and macro shocks, and show that the basic intuitions and results obtained in the stylized steady-state model are robust.

### 5.1. Notations and definitions

### 5.1.1. Demography.

We use a relatively standard, Solow-type model of capital accumulation and growth, but with a specific demographic structure. In order to obtain meaningful theoretical formulas for inheritance flows (i.e. formulas that can be used with real numbers), we need a dynamic model with a realistic demographic structure. Models with infinitely lived agents or perpetual youth models will not do, and standard two-period or three-period overlapping generations models will not do either.

To keep notations simple, we consider a continuous-time OLG model with the following deterministic, stationary demographic structure (see Figure 9). ${ }^{55}$ Everybody becomes adult at age $a=A$, has exactly one kid at age $a=H>A$, and dies at age $D>H$. As a consequence everybody inherits at age $\mathrm{a}=\mathrm{I}=\mathrm{D}-\mathrm{H}$. This is a gender free population. There is no inter vivos gift: all wealth is transmitted at death. Cohort $x$ is defined as the set of individuals born at time x . Each cohort size $\mathrm{N}^{\mathrm{x}}$ is normalized to 1 and includes a continuum [0;1] of agents. So at any time $t$, the living population includes a mass $N_{t}(a)=1$ of adult individuals of age a $(A \leq a \leq D)$. Total adult population $N_{t}$ is permanently equal to $D-A$. The adult mortality rate $m_{t}$ is also stationary and is given by:

$$
\begin{equation*}
m_{t}=m^{*}=\frac{1}{D-A} \tag{5.1}
\end{equation*}
$$

Example. Around 1900, we have $A=20, H=30$ and $D=60$, so that people inherit at age $I=D-$ $H=30$, and $m^{*}=1 /(D-A)=1 / 40=2.5 \%$. Around 2020, we have $A=20, H=30$ and $D=80$, so that people inherit at age $\mathrm{I}=\mathrm{D}-\mathrm{H}=50$, and $\mathrm{m}^{*}=1 /(\mathrm{D}-\mathrm{A})=1 / 60=1.7 \%$.

### 5.1.2. Production.

We assume a standard two-factor production function, with exogenous productivity growth:

$$
\begin{equation*}
Y_{t}=F\left(K_{t}, H_{t}\right)=F\left(K_{t}, e^{g t} L_{t}\right) \tag{5.2}
\end{equation*}
$$

[^26]With: $\mathrm{Y}_{\mathrm{t}}=$ national income
$\mathrm{K}_{\mathrm{t}}=$ physical (non-human) capital
$H_{t}=$ human capital $=$ efficient labor supply $=e^{g t} L_{t}$
$L_{t}=$ labor supply
$g$ = exogenous labor productivity growth rate

Since population $N_{t}=D-A$ is stationary, so is labor supply $\mathrm{L}_{\mathrm{t}}$. We assume that all adults inelastically supply one unit of labor each year from age a=A until some exogenous retirement age $a=R \leq D$ (say, $A=20$ and $R=60$ ), so that aggregate labor supply $L_{t}=R-A$.

So in the steady state of our model, everything will grow at some exogenous growth rate $g \geq 0$. One might want to plug in endogenous growth models into this setting. By doing so, one could generate interesting two-way interactions between growth and inheritance. ${ }^{56}$ However in order to simplify the analysis, and also because growth depends on so many factors on which we know relatively little, we choose in this paper to take the growth rate $g$ as given and to study its one-way impact on aggregate inheritance flows.

For notational simplicity, we also assume away government debt (and government assets). In the closed economy case (no foreign assets), ${ }^{57}$ private wealth $\mathrm{W}_{\mathrm{t}}$ is exactly equal to the domestic capital stock $\mathrm{K}_{\mathrm{t}}$, and the aggregate private wealth-national income ratio is exactly equal to the domestic capital-output ratio:

$$
\begin{equation*}
\beta_{t}=W_{t} / Y_{t}=K_{t} / Y_{t} \tag{5.3}
\end{equation*}
$$

We note $Y_{t}=Y_{K t}+Y_{L t}$ the functional distribution of income, with $Y_{K t}=$ capital income and $Y_{L t}=$ labor income. We note $\alpha_{t}=Y_{k_{t}} / Y_{t}$ the capital share, 1- $\alpha_{t}=Y_{L t} / Y_{t}$ the labor share, and $r_{t}$ the average rate of return to private wealth: $r_{t}=Y_{K_{t}} / W_{t}=\alpha_{t} / \beta_{t}$.

Example. Typically the wealth-income income ratio $\beta_{t}=600 \%$, the capital share $\alpha_{t}=30 \%$, and the average rate of return to private wealth $r_{t}=5 \%$.

[^27]For simplicity, we assume a Cobb-Douglas production function $F(K, H)=K^{\alpha} H^{1-\alpha}$, which as a first approximation seems to be a reasonably good description of the real world in the longrun. ${ }^{58}$ Together with the competitive factor markets assumption and the closed economy assumption, the Cobb-Douglas specification implies that the capital share $\alpha_{t}$ is permanently equal to $\alpha$, so that the rate of return is simply an inverse function of the wealth-income ratio: $r_{t}=\alpha / \beta_{t}$.

We note $y_{t}, w_{t}, y_{K t}, y_{L t}$ the per adult averages of all aggregate variables: $y_{t}=Y_{t} / N_{t}=y_{L t}+r_{t} w_{t}$, $w_{t}=W_{t} / N_{t}, y_{K t}=Y_{K t} / N_{t}=r_{t} W_{t}$, and $y_{L t}=Y_{L t} / N_{t}$. We use subscripts for time $t$, parentheses for age a and superscripts for cohort $x$. E.g. $y_{t}(a)$ is the average income at time $t$ of individuals aged a-year-old at that time (they belong to cohort $x=t-a$ ), $y_{t}^{x}$ is the average income at time $t$ of individuals who were born at time $x$ (they have age $a=t-x$ ), and $y^{x}(a)$ is the average income at age a of individuals who were born at time $x$ (this happens at time $t=x+a$ ).

The aggregate cross-sectional age-wealth and age-labor income profiles at time t are noted $w_{t}(a)$ and $y_{L_{t}}(a)$, and the aggregate longitudinal age-wealth and age-labor income profiles followed by cohort $x$ are noted $w^{x}(a)$ and $y_{L}{ }^{x}(a)$.

When we refer to particular individuals we use subscripts i. E.g. $\mathrm{y}_{\mathrm{Lt}}\left(\mathrm{resp} . \mathrm{w}_{\mathrm{ti}}\right)$ is the labor income (resp. the wealth) at time $t$ of a given individual $i$. In this paper, we are primarily interested in the evolution of aggregate ratios. We use linear saving models, which allow us to solve for aggregate evolutions without keeping track of the intra-cohort distributions of labor income and wealth. So we will mostly concentrate upon per adult averages $y_{t}, w_{t}$, $y_{L t}$ and age-level averages $y_{t}(a), w_{t}(a), y_{L t}(a)$. But it is worth noting that our results hold not only for the representative-agent interpretation of the model (zero intra cohort inequality), but also for any given level of permanent, intra-cohort labor income inequality stemming

[^28]from some exogenous heterogeneity in skills or luck or taste or effort, as well as for various structures of idiosyncratic shocks on saving behavior. ${ }^{59}$

### 5.1.3. Age-labor income profile and pension system

For simplicity, we assume that the cross-sectional age-labor income profile $y_{L t}(a)$ is flat among adult workers, i.e. all age groups between age $a=A$ and age $a=R$ have the same average labor income at any time t. ${ }^{60}$ This assumption of a flat cross-sectional age-labor income profile obviously does not apply to longitudinal profiles: with positive productivity growth $\mathrm{g}>0$, average labor income $\mathrm{y}_{\mathrm{Lt}}$ grows at rate g in steady-state, i.e. longitudinal agelabor income profiles are upward sloping.

We take as given the existence of an unfunded, pay-as-you-go pension system financed by a flat payroll tax rate $T_{\rho}$ on all adult workers and offering a flat replacement rate $\rho \leq 1$ to adults older than retirement age $R$. ${ }^{61}$ To simplify notations, we integrate pension income into labor income $y_{L t}(a)$. That is, $y_{L t}(a)$ is equal to "augmented labor income", which we define as net-of-pension-tax labor income for working adults $(A<a<R)$ and pension income for retired adults ( $\mathrm{R}<\mathrm{a}<\mathrm{D}$ )..$^{62}$ In effect we assume a simple two-tier cross-sectional agelabor income profile $y_{\mathrm{Lt}}(\mathrm{a})$ among adults (see Figure 10):

If $a \in\left[A, R\left[, y_{L t}(a)=\left(1-T_{\rho}\right) \hat{y}_{L t}\right.\right.$
If $a \in[R, D], y_{L t}(a)=\rho\left(1-T_{\rho}\right) \hat{y}_{L t}$

With: $\hat{y}_{\mathrm{Lt}}=\frac{\mathrm{D}-\mathrm{A}}{\mathrm{R}-\mathrm{A}} \mathrm{y}_{\mathrm{Lt}}=$ average pre-tax labor income of adult workers at time t
$T_{\rho}=$ budget-balanced pension tax rate $=\frac{\rho(D-R)}{R-A+\rho(D-R)}$

[^29]In order to offer 100\% replacement rates, the pension tax $T_{\rho}$ must by definition be equal to the share of pensioners in total adult population, which in the absence of population growth is simply equal to retirement length $D-R$ divided by total adult life length $D-A$.

In practice, pay-as-you-go pension systems offer significant replacement rates $\rho$ in most developed countries (usually over $50 \%$ ). In France, $\rho$ is currently about $70 \%-80 \% .{ }^{63}$ In the theoretical results below, we use $\rho$ as a free parameter of the model. When we set $\rho$ to $100 \%$, we effectively shut down the life-cycle saving motive. When we reduce $\rho$, we gradually make lifecycle wealth accumulation more important. This allows us to investigate the quantitative interaction between private wealth accumulation, inheritance flows and the generosity of pay-as-you-go pension systems.

### 5.1.4. Aggregate inheritance flow

Since each cohort size $N^{x}$ is normalized to 1 , the aggregate inheritance flow $B_{t}$ is equal to per decedent inheritance $b_{t}$. Since everybody dies at age $a=D$, per decedent inheritance $b_{t}$ is equal to the average wealth $w_{t}(D)$ of D-year-old individuals. ${ }^{64}$ So the ratio $\mu_{t}=b_{t} / w_{t}$ between average wealth of decedents and average wealth of the living is given by:

$$
\begin{equation*}
\mu_{t}=\frac{b_{t}}{w_{t}}=\frac{w_{t}(D)}{w_{t}} \tag{5.4}
\end{equation*}
$$

In order to compute the value of $\mu_{\mathrm{t}}$, we simply need to study the dynamics of the agewealth profile $w_{t}(a)$. The inheritance-income ratio $b_{y t}=B_{t} / Y_{t}=m_{t} \mu_{t} \beta_{t}$ and the inheritancewealth ratio $b_{w t}=B_{t} / W_{t}=m_{t} \mu_{t}$ are then given by applying accounting equations (3.1)-(3.3).

### 5.2. Steady-state inheritance flow in the exogenous savings model

We start by solving the model with exogenous saving rates. That is, we assume that the average saving rates out of labor income $s_{L}$ and out of capital income $s_{K}$ are the same for

[^30]all age groups (in particular there is no dissaving at old age). We take $\mathrm{s}_{\mathrm{L}}$ and $\mathrm{s}_{\mathrm{K}}$ as given and constant over time. ${ }^{65}$

A special case of this formulation is uniform savings: $\mathrm{s}_{\mathrm{L}}=\mathrm{S}_{\mathrm{K}}=\mathrm{s}$. Another special case is so called "class savings" ( $s_{L}=0$ and $s_{K}>0$ ), whereby savings come solely from capital income. In the general case ( $s_{L} \geq 0, s_{K} \geq 0$ ), the aggregate savings rate $s$ is given by $s=\alpha s_{K^{+}}+(1-\alpha) s_{L}$, where $\alpha$ is the Cobb-Douglas capital share.

The exogenous savings model is obviously not very satisfactory from an intellectual viewpoint. We later move to more micro founded models. ${ }^{66}$ However it provides a useful benchmark and helps to clarify some of the key intuitions. Also note that real world aggregate saving rates happen to be relatively flat with respect to age (consumption tends to track down income pretty closely), or at least much less age-dependant that what most micro models would tend to predict. ${ }^{67}$ Whatever the exact explanation for this fact might be (imperfect capital markets, imperfect foresight, etc.), it is useful to know what the implications are for the long dynamics of age-wealth profiles and inheritance flows. ${ }^{68}$

### 5.2.1. Steady-state wealth-income ratio and rate of return

A well know property of our Solow-type wealth accumulation model is that the long-run wealth-income ratio $\beta_{t}=W_{t} / Y_{t}$ and rate of return $r_{t}$ are uniquely determined: ${ }^{69}$

[^31]
## Proposition 1 (exogenous savings, closed economy)

Assume exogenous saving rates $s_{L} \geq 0, s_{K} \geq 0$. Note $s=\alpha s_{K}+(1-\alpha) s_{L}$ (aggregate savings rate). As $t \rightarrow+\infty$, the wealth-income ratio $\beta_{t}=W_{t} / Y_{t} \rightarrow \beta^{*}$ and the rate of return $r_{t} \rightarrow r^{*}$. Steady-state $\beta^{*}$ and $r^{*}$ are uniquely determined by: $\boldsymbol{\beta}^{*}=\mathbf{s} / \mathbf{g}$ and $\mathbf{r}^{*}=\boldsymbol{\alpha} / \boldsymbol{\beta}^{*}=\boldsymbol{\alpha g} / \mathbf{s}$

Example: If the savings rate $s=10 \%$ and the growth rate $g=2 \%$, then the long-run wealthincome ratio $\beta^{*}=500 \%$. If the Cobb-Douglas capital share $\alpha=30 \%$, then this corresponds to a long-run rate of return $r^{*}=6 \%$.

The Harrod-Domar-Solow formula $\beta^{*}=s / g$ is a pure accounting equation. It necessarily holds in steady-state, whatever the production function or the savings model might be. If the long run savings rate is equal to $s$, then in the long run $\beta^{*}$ converges toward $\mathrm{s} / \mathrm{g} .{ }^{70}$

In the Cobb-Douglas specification, the long run rate of return $r^{*}=\alpha g / s$ can in principle be larger or smaller than the growth rate g , depending on whether on the capital share $\alpha$ is larger or smaller than the savings rate $s$. In practice however, $\alpha$ is usually much larger $s$ in real world economies, so steady-state $r^{*}$ is larger than $\mathrm{g} .{ }^{71}$ In any case, the rate of return $r^{*}$ is always an increasing function of g . For a given saving rate, higher growth makes capital relatively scarcer, and therefore marginally more productive.

The rate of wealth reproduction $\mathrm{s}_{\mathrm{K}} \mathrm{r}^{*}$ is by construction always less than g in steady-state. Otherwise this would not be a steady-state: with $s_{k} r^{*}>g$, wealth holders accumulate new wealth at a faster rate than national income growth (even in the absence of any labor income), and the wealth-income ratio rises indefinitely. So $\mathrm{s}_{\mathrm{K}} \mathrm{r}^{*} \leq \mathrm{g}$. As long as $\mathrm{s}_{\mathrm{L}}>0$, one can see that $g-s_{k} r^{*}=g(1-\alpha) s_{\llcorner } / s$ is strictly positive: it is equal to the growth rate times the share of labor income savings in total savings. With uniform savings, it is simply equal to $(1-\alpha) g$. The equality $s_{k} r^{*}=g$ corresponds to the class savings case $s_{L}=0$ and $s_{k}>0$.

[^32]Example: With $\mathrm{s}_{\mathrm{L}}=0 \%, \mathrm{~s}_{\mathrm{K}}=20 \%, \mathrm{~g}=1 \%$ and $\alpha=30 \%$, then the aggregate savings rate $s=\alpha s_{k}=6 \%$. So the long-run wealth-income ratio $\beta^{*}=s / g=600 \%$, and the long-run rate of return $r^{*}=\alpha / \beta^{*}=5 \%$. Wealth holders get a $5 \%$ return, consume $80 \%$ of it and save $20 \%$, so that their wealth grows at $1 \%$, just like national income. This is a steady-state.

### 5.2.2. Steady-state inheritance flows: class savings case

How do the steady-state age-wealth profile $\mathrm{w}_{\mathrm{t}}(\mathrm{a})$, the $\mu_{\mathrm{t}}$ ratio and the inheritance flow ratios $b_{y t}$ and $b_{w t}$ look like in this well-known model? Consider first the class savings case: $s_{L}=0$, $s_{k}>0$. Then the steady-state age-wealth profile $w_{t}(a)$ takes a simple form (see Figure 11):

If $a \in\left[A, I\left[\right.\right.$, then $w_{t}(a)=0$
If $a \in[I, D]$, then $w_{t}(a)=\bar{w}_{t}$

Since $s_{L}=0$, young individuals have zero wealth until the time they inherit. Then, at age $a=1$, everybody inherits (some inherit very little or nothing at all, some inherit a lot, depending on the cross-sectional distribution, and on average they inherit $b_{t}=w_{t}(I)=w_{t}(D)$ ), so that average wealth $w_{t}(a)$ jumps to some positive level $\bar{w}_{t}=b_{t}$. Now, the interesting point is that in the cross-section all age groups with age a between I and D has the same average wealth $w_{t}(a)=\bar{w}_{t}$. This is because in steady-state the growth effect and the saving effect exactly compensate each other. Take the group of individuals with age $a>1$ at time $t$. They inherited $a-I$ years ago, at time $s=t-a+1$. They received average bequests $b_{s}=w_{s}(1)$ that are smaller than the average bequests $b_{t}=w_{t}(I)$ inherited at time $t$ by the l-year-old. Since everything grows at rate $g$ in steady-state, we simply have: $b_{s}=e^{-g(a-1)} b_{t}$. But although they received smaller bequests, they saved a fraction $s_{k}=g / r^{*}$ of the corresponding return, so at time $t$ their inherited wealth is now equal to: $w_{t}(a)=e^{s k r^{*}(a-l)} e^{-g(a-l)} b_{t}=b_{t}=w_{t}(I)=\bar{w}_{t}$.

Given this age-wealth profile, the average wealth $w_{t}$ over all age groups $a \in[A, D]$ is given by: $w_{t}=(D-I) \bar{w}_{t} /(D-A)=H \bar{w}_{t} /(D-A)$. It follows that the steady-state ratio $\mu^{*}=w_{t}(D) / w_{t}=\bar{w}_{t} / w_{t}$ is entirely determined by demographic parameters:

$$
\begin{equation*}
\mu^{*}=\frac{w_{t}(D)}{w_{t}}=\frac{D-A}{H} \tag{5.5}
\end{equation*}
$$

Once we know $\mu^{*}$, we can easily compute steady-state inheritance flow ratios $b_{w}{ }^{*}=m^{*} \mu^{*}$ and $b_{y}{ }^{*}=m^{*} \mu^{*} \beta^{*}$. Here the important point is that since the mortality rate $m^{*}=1 /(D-A)$, the product $m^{*} \mu^{*}$ is simply equal to one divided by generation length $H$, and does not depend on adult life length D-A. We summarize these observations in the following proposition:

## Proposition 2 (class savings, closed economy)

Assume pure class savings: $s_{L}=0 \& s_{k}>0$. As $t \rightarrow+\infty, \mu_{t \rightarrow} \rightarrow \mu^{*}, b_{w t} \rightarrow b_{w}{ }^{*}$ and $b_{y t} \rightarrow b_{y}{ }^{*}$.
Steady-state ratios $\mu^{*}, b_{w}{ }^{*}$ and $b_{y}{ }^{*}$ are uniquely determined as follows:
(1) The ratio $\mu^{*}$ between average wealth of decedents and average adult wealth depends solely on demographic parameters: $\mu^{*}=\bar{\mu}=(D-A) / H(>1)$.
(2) The inheritance flow-private wealth ratio $b_{w}{ }^{*}=\mu^{*} m^{*}$ and the estate multiplier $e^{*}=1 / b_{w}{ }^{*}$ depend solely on generation length $H: b_{w}{ }^{*}=\bar{b}_{w}=1 / H$ and $e^{*}=\bar{e}=H$
(3) The inheritance flow-national income ratio $b_{y}{ }^{*}=\mu^{*} m^{*} \beta^{*}$ depends solely on the aggregate wealth-income ratio $\beta^{*}$ and on generation length $H: \quad \mathbf{b}_{y}{ }^{*}=\bar{b}_{y}=\boldsymbol{\beta}^{*} / H$

Proposition 2 is simple, but powerful. It holds for any growth rate g, saving rate $\mathrm{s}_{\mathrm{K}}$, and life expectancy $D$. It says that societies with a higher life expectancy $D$ will have both lower mortality rates $m_{t}$ and higher $\mu_{t}$ ratios, and that in steady state both effects will exactly compensate each other, so that the product of the two does not depend on life expectancy. The product $b_{w t}=m_{t} \mu_{t}$ will only depend on generation length $H$, i.e. the average age at which people have children - a parameter which has been relatively constant over the development process (around $\mathrm{H}=30$ ). If we assume that the wealth-income ratio $\beta^{*}$ also tends to be constant in the long run (around $\beta^{*}=600 \%$ ), then we have a simple explanation as to why the aggregate inheritance flow $b_{y}{ }^{*}=\beta^{*} / \mathrm{H}$ always seems to return to approximately $20 \%$ of national income.

The intuition is the following: in aging societies with higher life expectancy, people die less often, but they die with higher relative wealth, so that the aggregate inheritance flow is unchanged. In effect, the entire wealth profile is simply shifted towards older age groups: one has to wait longer before inheritance, but one inherits larger amounts, so that from a lifetime perspective inheritance is just as important as before. ${ }^{72}$

Example. Assume $\beta^{*}=600 \%$ and $H=30$. Then $b_{w}{ }^{*}=1 / H=3.3 \%$ and $b_{y}{ }^{*}=\beta^{*} / H=20 \%$.

[^33]I.e. the aggregate inheritance flow equals $20 \%$ of national income, irrespective of other parameter values, and in particular irrespective of life expectancy $D$.

- Around 1900, we have $A=20, H=30$ and $D=60$, so that people inherit at age $I=D-H=30$. In steady-state, $m^{*}=1 /(D-A)=2.5 \%$ and $\mu^{*}=(D-A) / H=133 \%$. Then $b_{w}{ }^{*}=m^{*} \mu^{*}$ equals $3.3 \%$ of private wealth and $b_{y}{ }^{*}=m^{*} \mu^{*} \beta^{*}$ equals $20 \%$ of national income.
- Around 2020, we have $A=20, H=30$ and $D=80$, so that people inherit at age $I=D-H=50$. In steady-state, $m^{*}=1 /(D-A)=1.7 \%, \mu^{*}=(D-A) / H=200 \%$. Then $b_{w}{ }^{*}=m^{*} \mu^{*}$ again equals $3.3 \%$ of private wealth and $b_{y}{ }^{*}=m^{*} \mu^{*} \beta^{*}$ again equals $20 \%$ of national income.

Although this is a very crude model, we believe that this simple result provides the right intuition as to why the historical decline in mortality rates was to a large extent compensated by an historical rise in the relative wealth of decedents. Moreover, as we see below, this intuition obtained in the class savings model generalizes to more general savings behaviour, assuming that the growth rate g is relatively small.

The discontinuous age-wealth profile obtained in this model (see Figure 11) is obviously an artefact due to the deterministic demographic structure, and would immediately disappear once one introduces demographic noise (as there is in the real world), without affecting the results. E.g. assume that individuals, instead of dying with certainty at age $a=D$, die at any age on the interval [D-d;D+d], with uniform distribution. Then individuals will inherit at any age on the interval [l-d;I+d]. To fix ideas, say that $A=20, H=30, D=70$ and $d=10$, i.e. individuals die at any age between 60 and 80 , with uniform probability, and therefore inherit at any age between 30 and 50, with uniform probability. Then one can show that the steady-state age-wealth profile has a simple linear shape (see Figure 12), and that the theoretical results of proposition 2 are wholly unaffected. ${ }^{73}$

In the real world, there are several other types of demographic noise (age at parenthood is not the same everybody, fathers and mothers usually do not die at the same time, there is differential mortality, there are inter vivos gifts, etc.), and we take all of these into account in the full fledged simulated model. The important point, however, is that the basic intuition provided by proposition 2 is essentially unaffected by demographic noise.

[^34]
### 5.2.4. Steady-state inheritance flow: general case

In the general case ( $s_{L} \geq 0 \& s_{k} \geq 0$ ), one can show that steady-state inheritance ratios depend negatively on the growth rate, and converge towards class saving levels as $\mathrm{g} \rightarrow 0$ :

## Proposition 3 (exogenous savings model, closed economy)

Assume exogenous saving rates $s_{L}>0, s_{k} \geq 0$. As $t \rightarrow+\infty, \mu_{t} \rightarrow \mu^{*}=\mu(g)<\bar{\mu}$
Higher growth reduces the relative importance of inheritance: $\mu^{\prime}(\mathrm{g})<0$
With low growth, inheritance ratios converge to class saving levels: $\lim _{\mathbf{g} \rightarrow 0} \boldsymbol{\mu}(\mathbf{g})=\bar{\mu}$

Proposition 3 is a generalization of Proposition 2 and includes it as a special case. The general formula for steady-state $\mu^{*}=\mu(\mathrm{g})$ turns out to be reasonably simple:

$$
\begin{equation*}
\mu(\mathrm{g})=\frac{1-\mathrm{e}^{-\left(\mathrm{g}-\mathrm{sk} \mathrm{~K}^{\star}\right)(\mathrm{D}-\mathrm{A})}}{1-\mathrm{e}^{-\left(\mathrm{g}-\mathrm{sk} \mathrm{r}^{2}\right) H}} \tag{5.6}
\end{equation*}
$$

With $s_{L}>0$, the steady-state rate of wealth reproduction $s_{K} r^{*}$ is strictly less than the growth rate $g$, and $g-s_{K} r^{*}=g(1-\alpha) s_{L} / s>0$. If $s_{L} \rightarrow 0$, then $g-s_{K} r^{*} \rightarrow 0$. Simple first order approximation using the formula $\mu(\mathrm{g})$ shows that steady-state $\mu^{*}$ then tends toward $\bar{\mu}=(\mathrm{D}-\mathrm{A}) / \mathrm{H}^{74}$ This is just a continuity result: as we get closer to class savings, we converge toward the same age-wealth profile and inheritance ratios, whatever the growth rate might be.

The more interesting part of Proposition 3 is that for any saving behaviour ( $s_{L}>0, s_{k} \geq 0$ ), steady-state $\mu^{*}$ also tends toward the same class-saving level $\bar{\mu}$ when the growth rate $g$ tends toward 0 . In the uniform savings case ( $\left.s_{L}=s_{K}=s\right), g-s_{k} r^{*}=(1-\alpha) g$, so we simply have:

$$
\begin{equation*}
\mu(\mathrm{g})=\frac{1-\mathrm{e}^{-(1-\alpha) g(\mathrm{D}-\mathrm{A})}}{1-\mathrm{e}^{-(1-\alpha) g H}} \tag{5.7}
\end{equation*}
$$

First-order approximations again show that $\mu(\mathrm{g}) \rightarrow \bar{\mu}$ as $g \rightarrow 0$. Steady-state inheritance ratios $b_{w}{ }^{*}$ and $b_{y}{ }^{*}$ also tend toward their class saving levels $\bar{b}_{w}=1 / H$ and $\bar{b}_{y}=\beta^{*} / H$ when growth rates go to zero. Conversely, the higher the growth rate g , the lower the steadystate inheritance ratios $\mu^{*}=\mu(\mathrm{g}), \mathrm{b}_{\mathrm{w}}{ }^{*}$ and $\mathrm{b}_{\mathrm{y}}{ }^{*}$.

[^35]The intuition is the following. With $s_{L}>0$, the age-wealth profile is less extreme than the class saving profile depicted on Figure 11. Young workers now accumulate positive wealth before they inherit (and accumulate positive wealth even if they never inherit). So the relative wealth of the elderly $\mu_{\mathrm{t}}$ will always be lower than under class savings. Since labor income grows at rate g , this effect will be stronger for higher growth rates. With large growth, young workers earn a lot more than their parents. This reduces the importance of inheritance. But with low growth, the inheritance effect increasingly dominates, and the steady-state age-wealth profile looks closer and closer to the class saving profile. So inheritance flows converge towards class saving levels, irrespective of saving behavior. ${ }^{75}$

Next, and most importantly, formulas (5.6)-(5.7) can be used to quantify the magnitude of the effects at play. The point is that convergence towards class saving levels happens very fast. That is, for low but realistic growth rates (typically, $g=1 \%$ or $g=2 \%$ ), we find that $\mu(\mathrm{g})$ is already very close to $\grave{\rho}$. That is, inheritance-wise, a growth rate of $\mathrm{g}=1 \%$ or $\mathrm{g}=2 \%$ is not very different from a growth rate $\mathrm{g}=0 \%$.

Example. Assume $g=1 \%$ and uniform savings ( $s=s_{K}=s_{L}$ ). Then for $A=20, H=30, D=60$, i.e. $\mathrm{I}=\mathrm{D}-\mathrm{H}=30$, we have $\mu(\mathrm{g})=129 \%$. This is lower than $\bar{\mu}=(\mathrm{D}-\mathrm{A}) / \mathrm{H}=133 \%$ obtained under class savings, but not very much lower. With $\beta^{*}=600 \%$, this corresponds to $b_{y}{ }^{*}=19 \%$ instead of $b_{y}{ }^{*}=20 \%$ under class savings. With $A=20, H=30, D=80$, i.e. $I=D-H=50$, we get $\mu(g)=181 \%$ under uniform savings instead of $\bar{\mu}=200 \%$ with class savings, and again $b_{y}{ }^{*}=19 \%$ instead of $b_{y}{ }^{*}=20 \%$. Assuming $g=2 \%$, we still get $b_{y}{ }^{*}=19 \%$ with $D=60$, and $b_{y}{ }^{*}=17 \%$ with $D=80$, instead of $b_{y}{ }^{*}=20 \%$ in both cases under class savings. ${ }^{76}$

Assume for instance that there was a major structural shift from class saving behaviour in the $19^{\text {th }}$ century to uniform savings in the $20^{\text {th }}$ century (or even to reverse class saving, where all savings come from labor income), for instance because of a structural decline in wealth concentration. This will tend to make wealth less persistent over time, and therefore to reduce the steady-state magnitude of inheritance flows. However with growth rates

[^36]around $\mathrm{g}=1 \%-2 \%$ the effect will be quantitatively extremely modest: the annual inheritance flow will be $17 \%-19 \%$ of national income instead of $20 \%$.

In order to obtain more substantial declines in $\mu^{*}$ and $b_{y}{ }^{*}$, one needs to assume much larger growth rates. E.g. with $g=5 \%$, then one gets $b_{y}{ }^{*}=17 \%$ with $D=60$, and $b_{y}{ }^{*}=13 \%$ with $D=80$ (again for $\beta^{*}=600 \%$ ). This can contribute to explain why inheritance flows remained low during the 1950s-1970s period, when growth rates were indeed exceptionally high. ${ }^{77}$

As $g \rightarrow+\infty$, then $\mu^{*}=\mu(g) \rightarrow 1, b_{w}{ }^{*} \rightarrow 1 /(D-A)$ and $b_{y}{ }^{*} \rightarrow \beta^{*} /(D-A)$. Assume $D=80$, so that adult life length $D-A=60$ is twice as long as generation length $H=30$. Then infinite growth leads to a doubling of the estate multiplier $e^{*}$ (from $e^{*}=30$ to $e^{*}=60$ ), and a division by two of the inheritance flow $b_{y}{ }^{*}$ (from $b_{y}{ }^{*}=20 \%$ to $b_{y}{ }^{*}=10 \%$, for given $\beta^{*}=600 \%$ ). In case life expectancy rises to $D=110$, then the inheritance flow is divided by three. With infinite growth, $b_{w}{ }^{*} \rightarrow 0$ and $b_{y}{ }^{*} \rightarrow 0$ as $D \rightarrow+\infty$. That is, societies where people die later and later resemble societies where one never dies, and inheritance effectively vanishes. The key point, however, is that this naive intuition only applies to the case with infinite growth. With plausible growth rates, then the inheritance flow $b_{y}{ }^{*}$ depends almost exclusively on generation length H , and is little affected by the rise of life expectancy D .

The generosity of the pay-as-you-go pension system also has a limited impact on inheritance flows in this model. Under class savings, the replacement rate $\rho$ has no impact at all, since there is no saving from labor income. With $s_{L}>0$, the replacement rate has an effect going in the expected direction: lower pensions make the elderly relatively poorer, thereby reducing $\mu^{*}$ and $b_{y}{ }^{*}$. But for small growth rates, the quantitative impact is again limited. E.g. with $g=1 \%$ and $D=80$, then going from $\rho=100 \%$ to $\rho=0 \%$ (no pension at all) makes $b_{y}{ }^{*}$ go from $18 \%$ to $17 \%{ }^{78}$ However this is partly an artefact due to the exogenous saving modelling. Here the impact of the pension system is by construction solely due to the mechanical effect going through age-income profiles (for fixed saving rates). In the real world, if there was no pension system at all, at least some individuals would presumably react by saving more while active and by dissaving while retired, i.e. they would adopt non-

[^37]flat age-saving rates profiles and accumulate lifecycle wealth. In order to address this issue, one needs to use endogenous saving models, which we do below.

### 5.2.4. Open economy

So far we could not study separately the effect of $g$ and $r$ on steady-state inheritance flows, since $r=r^{*}$ was entirely determined by $g$ in the long run. This followed from the closed economy assumption. So consider now the opposite extreme case of a small open economy taking as given the world rate of return $r>0$. We have the following result:

## Proposition 4 (exogenous savings model, open economy).

Assume exogenous saving rates $s_{L} \geq 0, s_{k} \geq 0$, and a world rate of return $r \geq 0$.
As $t \rightarrow+\infty, \mu_{t} \rightarrow \mu^{*}=\mu(g, r)$. If $r>\bar{r}=g / s_{k}$, then $\mu(g, r)=\bar{\mu}$. If $r<\bar{r}$, then $\mu(g, r)<\bar{\mu}$.
Lower growth and/or higher rates of return raise the relative importance of inheritance: $\mu^{\prime}(\mathrm{g})<0, \mu^{\prime}(\mathrm{r})>0$.
With low growth and/or high rates of return, inheritance ratios converge to class saving levels: $\lim _{\mathbf{g} \rightarrow 0} \boldsymbol{\mu}(\mathbf{g}, \mathbf{r})=\lim _{r \rightarrow \bar{r}} \boldsymbol{\mu}(\mathbf{g}, \mathbf{r})=\bar{\mu}$

Strictly speaking, the case $r>\bar{r}$ cannot be a long run outcome. With $s_{k} r>g$, wealth holders in our small open economy accumulate an infinite quantity of foreign assets (relatively to domestic output and domestic assets) and eventually become the owners of the entire world. This in principle should push downwards the world rate of return r. But it takes a long time to own the entire world. So such a process can apply during many decades. This model is useful to understand the wealth accumulation patterns prevailing in France (and other European countries such as the U.K.) in the $19^{\text {th }}$ century and early $20^{\text {th }}$ century. The French $\beta_{t}$ rose from $550 \%-600 \%$ in 1820 to $650 \%-700 \%$ in $1900-1910$, and most of the rise came from the accumulation of foreign assets. The case $r>\bar{r}$ is indeed particularly likely to prevail in environments with low growth and high wealth concentration (so that wealth holders can afford re-investing a large fraction $s_{K}$ of their asset returns). E.g. with $g=1 \%$ and $s_{K}=25 \%$, the world rate of return $r$ simply needs to be larger than $\bar{r}=\mathrm{g} / \mathrm{s}_{\mathrm{K}}=4 \%$. So if $r=5 \%$, then $s_{k} r=1.25 \%$, i.e. private wealth grows $25 \%$ faster than domestic output, which over a few decades makes a big difference.

What we add to these well-know open economy insights is the inheritance dimension. The interesting result here is that in case $r>\bar{r}$ then $\mu_{t}$ always converges towards its maximum class-saving level $\bar{\mu}$, whatever the growth rate $g$ and the labor saving rate $s_{L}$. That is, $g$ or
$s_{L}$ do not need to be infinitely small: they just need to be such that $r>\bar{r}$. Intuitively, labor income as a whole matters less and less along such explosive paths, and the age-wealth profile becomes almost exclusively determined by inheritance receipts.

The case $\mathrm{r}<\overline{\mathrm{r}}$ corresponds to balanced open-economy development paths. In steady-state the stock of net foreign assets (positive or negative) is a constant fraction of domestic output and assets. Here the steady-state $\mu^{*}=\mu(\mathrm{g}, \mathrm{r})$ is determined by the same formula as in the closed economy case, except that now both $g$ and $r$ are free parameters:

$$
\begin{equation*}
\mu(g, r)=\frac{1-e^{-(g-S K r)(D-A)}}{1-e^{-(g-s k r) H}} \tag{5.8}
\end{equation*}
$$

The intuition for $\mu^{\prime}(\mathrm{g})<0$ is the same as before: higher growth raises the relative wealth of the young and reduces the relative wealth of elderly (and therefore the relative importance of inheritance). The intuition for $\mu^{\prime}(r)>0$ is the opposite: a higher rate of return gives more weight to past inheritance and raises the relative wealth of the elderly.

In the same way as in the closed economy case, the important point about this formula is that it converges very fast to class saving levels as $g \rightarrow 0$ and/or as $r \rightarrow \bar{r}$.

The formula $\mu(\mathrm{g}, \mathrm{r})$ also shows that the $g$ effect is quantitatively larger than the $r$ effect, because the $r$ effect is multiplied by $\mathrm{s}_{K}<1$. That is, the absolute growth rate $g$ matters, and not only the differential $\mathrm{r}-\mathrm{g}$. For given $\mathrm{r}-\mathrm{g}$, the steady-state $\mu^{*}=\mu(\mathrm{g}, \mathrm{r})$ and the corresponding $b_{y}{ }^{*}$ will be lower for higher $g$.

Example. Assume $r-g=3 \%, \mathrm{D}=80, \mathrm{~s}_{\mathrm{K}}=20 \%$. If $\mathrm{g}=1 \%$ and $\mathrm{r}=4 \%$, then we obtain $\mu^{*}=\mu(g, r)=194 \%$ and $b_{y}{ }^{*}=19 \%$ (i.e. almost as much as the class saving levels $\bar{\mu}=200 \%$ and $\left.b_{y}{ }^{*}=20 \%\right)$. But if $g=5 \%$ and $r=8 \%$, then we get $\mu^{*}=\mu(g, r)=136 \%$ and $b_{y}{ }^{*}=14 \%{ }^{79}$

### 5.3. Steady-state inheritance flow in the dynastic model

We now move to the infinite-horizon, dynastic model. Each dynasty i is assumed to maximize a utility function of the following form:

[^38]\[

$$
\begin{equation*}
U_{i}=\int_{t \geq s} e^{-\theta t} u\left(c_{t i}\right) d t \tag{5.9}
\end{equation*}
$$

\]

Where $\theta$ is the rate of time preference, $\mathrm{c}_{\mathrm{t} i}$ is the consumption flow of dynasty i at time t , and $u(c)=c^{1-\sigma} /(1-\sigma)$ is a standard utility function with constant intertemporal elasticity of substitution (IES). The constant IES is equal to $1 / \sigma$. Realistic values for the IES are usually considered to be relatively small (typically between 0.2 and 0.5 ), and in any case smaller than one, i.e. $\sigma$ is a parameter that is typically bigger than one.

As is well known, the closed-economy steady-state rate of return $r^{*}$ in dynastic models is uniquely determined by the modified Ramsey-Cass golden rule of capital accumulation: ${ }^{80}$

$$
\begin{equation*}
\mathbf{r}^{*}=\theta+\sigma \mathbf{g} \tag{5.13}
\end{equation*}
$$

The special case $g=0$ implies $r^{*}=\theta$. More generally, for $g \geq 0$, the steady-state rate of return $r^{*}$ is always larger than the growth rate g in the dynastic model. ${ }^{81}$ In the same way as in the exogenous saving model, $\mathrm{r}^{*}$ is also an increasing function of $\mathrm{g} .{ }^{82}$

Once $r^{*}$ is uniquely determined, other aggregates follow. With Cobb-Douglas production, the steady-state wealth-income ratio $\beta_{t}=W_{t} / Y_{t}$ is uniquely determined by: $\beta^{*}=\alpha / r^{*}$.

Example: If $\theta=1 \%, \sigma=2, g=2 \%$, then $r^{*}=5 \%$. If $\alpha=30 \%$, then $\beta^{*}=600 \%$.

It is also well known that any wealth distribution such that the aggregate wealth-income ratio is equal to $\beta^{*}$ is a steady-state of the dynastic model. ${ }^{83}$ Because of the OLG

[^39]demographic structure, we need to specify how various generations of the same dynasty act with one another when they are alive at the same time. Consider a dynasty i with successive generations born at time $x_{i}, x_{i}+H, x_{i}+2 H$, etc. At time $t \in\left[x_{i}+H, x_{i}+D\right]$, generation $x_{i}$ has age $a \in[H, D]$, and his child born at time $x_{i}+H$ is also alive and has age $a \varepsilon[0, I]$. We do not want to enter into the modelling of inter vivos gifts, so for simplicity we assume that parents start to care about their children's consumption level only after they die. That is, we assume that generation $x_{i}$ is maximizing $U_{i}=\int_{t \geq s} e^{-\theta t} u\left(c_{t i}\right) d t$ with $s=x_{i}+A$, and where $c_{t i}$ denotes the consumption path followed by generation $x_{i}$ for $t \varepsilon\left[x_{i}+A, x_{i}+D\right]$, by generation $x_{i}+H$ for $t \in\left[x_{i}+D, x_{i}+D+H\right]$, and so on. We start with the simplest case:

## Proposition 5: (dynastic model, closed economy)

Assume $\rho=1$, and no borrowing against future inheritance.
Then inheritance ratios in the dynastic model are the same as in the class saving model.
As $t \rightarrow+\infty, \mu_{t} \rightarrow \bar{\mu}=(D-A) / H, b_{w t} \rightarrow \bar{b}_{w}=1 / H$ and $b_{y t} \rightarrow \bar{b}_{y}=\beta^{*} / H$

The intuition for this result is the following. Since the pay-as-you-go pension system offers $100 \%$ replacement rates $(\rho=1)$, there is no need at all for lifecycle saving. We also assume that young age agents cannot borrow against their future inheritance, which in the real world is indeed difficult, if not impossible. ${ }^{84}$ With these two assumptions, the consumption and wealth profiles look exactly the same as in the class saving model (see Figure 11):

If $a \in\left[A, I\left[, c_{t}(a)=y_{L t}(a)\right.\right.$ and $w_{t}(a)=0$
If $a \in[I, D], c_{t}(a)=y_{L t}(a)+\left(r^{*}-g\right) \bar{w}_{t}$ and $w_{t}(a)=\bar{w}_{t}$

That is, until the time they inherit, young workers simply consume their labor income ( $\mathrm{s}_{\mathrm{L}}=0$ ) and accumulate no wealth. Then they inherit. They still consume their full labor income, and in addition they can now consume a fraction $1-s_{k}$ of the return to their inherited wealth, and save the rest, with $s_{k}=g / r^{*}$. The growth and saving effects again cancel out, so that everybody above inheritance age has the same wealth $\bar{w}_{t}$. The reason why dynastic

[^40]agents behave in the same way as in the exogenous class saving model (with a marginal propensity to save out of labor income $s_{L}=0$, and a marginal propensity to save out of capital income $s_{K}=g / r^{*}$ ) can be phrased as follows. In this deterministic model, the consumption path of every dynasty (poor or rich) grows at rate g in steady-state. Since labor income naturally grows at rate g, zero-wealth dynasties do not need to save out of labor income. However wealth does not naturally grows at rate g. So if wealthy dynasties do not save, and instead consume the full return to their inherited wealth, then their future consumption will not grow. In order to make sure that their wealth and future capital income grows at rate $g$, they need to save a fraction $s_{k}=g / r^{*}$. Now, because $r^{*}>g$, $S_{K}=g / r^{*}<100 \%$ : wealthy dynasties consume a positive fraction $1-\mathrm{g} / \mathrm{r}^{*}$ of the return to their inherited wealth and save the rest.

Therefore the relative wealth of decedents $\mu_{\mathrm{t}}$ converges towards class saving level $\bar{\mu}$, and the inheritance ratios $b_{w t}$ and $b_{y t}$ converge toward $1 / H$ and $\beta^{*} / H$. So if $H=30$ and $\beta^{*}=600 \%$, then the dynastic model predicts that the inheritance flow should be equal to $20 \%$ of national income, whatever the growth rate $g$ and life expectancy $D$ might be.

If we allow for borrowing against future inheritance, and we solve for the time-consistent steady-state (whereby parents anticipate that their children borrow against future inheritance and adjust their saving behaviour accordingly), we find that inheritance ratios will be even larger than the class saving levels. Intuitively, parents leave larger bequests so as to compensate for the fact that children consume part of it before they die:

## Proposition 6: (dynastic model, closed economy)

Assume $\rho=1$, and borrowing against future inheritance.
Then inheritance ratios in the dynastic model are larger than in the class saving model.
As $t \rightarrow+\infty, \mu_{t} \rightarrow \mu^{*}=\frac{e^{(r-g)(D-A)}-1}{e^{(r-g) H}-1}>\bar{\mu}, b_{w t} \rightarrow b_{w}{ }^{*}>1 / H$ and $b_{y t} \rightarrow b_{y}^{*}>\beta^{*} / H$

The borrowing effect can be very large ( $b_{y}{ }^{*}$ can be well above $20 \%$ ). ${ }^{85}$ But we are not sure that the full borrowing case is empirically relevant. The results obtained with $\rho<1$ and noborrowing are probably more relevant:

## Proposition 7: (dynastic model, closed economy)

[^41]Assume $\rho<1$, and no borrowing against future inheritance.
Then inheritance ratios in the dynastic model are smaller than in the class saving model.
As $t \rightarrow+\infty, \mu_{t} \rightarrow \mu^{*}=\bar{\mu}\left[1-\frac{(1-\alpha) \beta_{\mathrm{L}}}{\beta^{*}}\right]$ (with $\beta_{\mathrm{L}}=$ lifecycle wealth in years of labor income)

If the pay-as-you-go pension system offers replacement rates below $100 \%$, then utility maximizing agents will start accumulating lifecycle wealth $\mathrm{w}_{\mathrm{Lt}}(\mathrm{a})$, i.e. hump-shaped wealth with maximal value at retirement age $a=R$ and going to zero as $a \rightarrow D$. Typically this takes the form of private pension funds. In the context of the dynastic model, this extra form of wealth accumulation will entirely crowd out other forms of wealth (since the aggregate wealth-income ratio $\beta^{*}=\alpha / r^{*}$ is fixed). So for instance if lifecycle wealth represents half of aggregate wealth, then steady-state inheritance ratios will be divided by two.

One can show that steady-state lifecycle wealth $\beta_{\mathrm{L}}=\mathrm{w}_{\mathrm{Lt}} / \mathrm{y}_{\mathrm{Lt}}$ in this model is given by a relatively simple closed form formula, which we calibrate in order to estimate the size of this effect. If there is no capitalization effect ( $r-g=0$ ), and no pension system at all ( $\rho=0$ ), then $\beta_{\mathrm{L}}$ is given by the standard Modigliani triangle formula. $\beta_{\mathrm{L}}$ is negligible when retirement length $D-R$ is low, e.g. in the $19^{\text {th }}$ century and early $20^{\text {th }}$ century (indeed it is null if $R=D=60$ ). But for late $20^{\text {th }}$ century and early $21^{\text {st }}$ century parameters (say, $R=60$ and $D=70$ or $D=80$ ), then $\beta_{L}$ can be as large as $400 \%-600 \%$. In theory it can therefore absorb a very large fraction of $\beta^{*}$. With $r-g>0, \beta_{L}$ is reduced significantly: lifecycle savers benefit from a capitalization effect, so they do not need to save and accumulate as much. Most importantly, pay-as-you go pension systems are an important feature of the real world, and they reduce drastically the need for lifecycle wealth accumulation.

Example. Assume $r^{*}=\theta+\sigma g=5 \%$ and $\alpha=30 \%$, so that $\beta^{*}=600 \%$. Assume that the pension system offers a replacement rate $\rho=80 \%$, which is roughly the case in France. Then we find that utility maximizing agents will accumulate lifecycle wealth (1- $\alpha$ ) $\beta_{\mathrm{L}}$ around $40 \%$ of national income for $D=70$ and $80 \%$ of national income for $D=80$. That is, lifecycle wealth is predicted to represent around $10 \%$ of aggregate wealth accumulation. ${ }^{86}$ Consequently, the theoretical formulas indicate that the inheritance flow $b_{y}{ }^{*}$ should be about $18 \%$ of national income (rather than $20 \%$ in the case $\rho=1$ ). The crowding out impact of lifecycle wealth is only slightly larger with higher growth rates. In case $\rho=50 \%$, then the crowding out effect is

[^42]much larger: with $g=2 \%, b_{y}{ }^{*}$ falls to $16 \%$ if $D=70$ and to $13 \%$ if $D=80$. With $\rho=0 \%$ (i.e. no pension system at all), $b_{y}{ }^{*}$ falls to $12 \%$ if $D=70$ and to $7 \%$ if $D=80 .{ }^{87}$

These results suggest that the generosity of public pension system can be an important determinant of inheritance flows in advanced economies - together with the growth rate. The dynastic model predicts that steady-state inheritance flows would be approximately divided by two if the pay-as-you-go pension system was abolished. With more realistic pension reforms, the effects are less spectacular, but still significant. E.g. the dynastic model predicts that for a given growth rate (say, g=2\%), countries with replacement rates around $70 \%-80 \%$ (such as France or Germany) should have inheritance flows $b_{y}{ }^{*}$ around $18 \%$ of national income, while countries with replacement rates around $50 \%$ (such as the U.K. or the U.S) should have inheritance flows around $14 \%-15 \%$ of national income.

These illustrative computations should however be viewed as upper bound estimates of the likely negative impact of lifecycle wealth on inheritance flows. We assume that young workers have perfect foresight and save whatever it takes in order to suffer zero consumption loss at retirement, which might not hold empirically. ${ }^{88}$ Most importantly, the $100 \%$ crowding out property of the dynastic model is rather extreme, and seems at odd with available evidence. ${ }^{89}$ Other models, such as the wealth-in-the-utility model, have less extreme implications. When the lifecycle saving motive becomes more important, then steady-state aggregate wealth accumulation $\beta^{*}$ also rises (and the rate of return $r^{*}$ declines), so that crowding out is only partial. The fact that $r^{*}$ and $\beta^{*}$ are entirely pinned down by preference and technology parameters in the dynastic model ( $r^{*}=\theta+\sigma \mathrm{g}, \beta^{*}=\alpha / r^{*}$ ) has extreme implications regarding other policy issues, which also seem to be at odd with empirical evidence. E.g. the dynastic model implies that when the capital income tax rate $\mathrm{T}_{\mathrm{K}}$ rises from $0 \%$ to $30 \%-40 \%$ (which is roughly what happened during the $20^{\text {th }}$ century), then $\beta^{*}$ should also decline by $30 \%-40 \%$, so that the after-tax rate of return $\left(1-\tau_{K}\right) r^{*}$ remains the same as before. Prima facie, the long run $\beta^{*}$ appears to have been relatively stable around $600 \%$, and after-tax returns seem to have declined accordingly. ${ }^{90}$

[^43]Another reason why lifecycle wealth might not fully crowd out other forms of wealth is the fact that pension funds can be invested in foreign assets - thereby raising the economy's $\beta^{*}$ without affecting the rate of return. But again this cannot be addressed in the context of the dynastic model, since opening up the economy leads to degenerate outcomes. If the world rate of return $r$ is above $r^{*}=\theta+\sigma g$, then the economy accumulates an infinite quantity of foreign assets and eventually owns the rest of the world. And if $r$ is below $r^{*}$, then the economy borrows indefinitely and is eventually owned by the rest of the world. In order to study open economy issues, one needs to use less extreme models.

### 5.4. Steady-state inheritance flow in the wealth-in-the-utility model

We now move to the finite-horizon, wealth-in-the-utility model. Each agent $i$ is assumed to maximize a utility function of the following form:

$$
\begin{equation*}
V_{i}=V\left(U_{C i}, w_{i}(D)\right) \tag{5.14}
\end{equation*}
$$

With: $U_{C i}=\left[\int_{A \leq a \leq D} e^{-\theta(a-A)} C_{i}(a)^{1-\sigma} d a\right]^{\frac{1}{1-\sigma}}$
$V(U, w)=\left(1-s_{B}\right) \log (U)+s_{B} \log (w)$
$S_{B}=$ share of lifetime resources devoted to end-of-life wealth $w_{i}(D)$
$1-s_{B}=$ share of lifetime resources devoted to lifetime consumption flow $c_{i}(a)(a \bullet[A, D])$
$\theta=$ rate of time preference, $1 / \sigma=$ intertemporal elasticity of substitution

One standard interpretation for this formulation is that agents care directly about the bequest $b_{i}=W_{i}(D)$ which they leave to the next generation. It could also be that they care about what wealth brings to them. In the presence of uninsurable lifetime shocks (income, health, time of death), people might like the security that goes with wealth. So this utility function can be interpreted as a reduced form for precautionary savings. ${ }^{91}$ People might also derive direct utility from the prestige, power and social status conferred by wealth. ${ }^{92}$ Presumably the exact combination of these saving motives varies a lot across individuals, just like other tastes. ${ }^{93}$ Whatever the interpretation, we have the following results:

[^44]
## Proposition 8 (wealth-in-the-utility model, closed economy)

As $t \rightarrow+\infty, \mu_{t} \rightarrow \mu^{*}=\mu(g), b_{w t} \rightarrow b_{w}{ }^{*}=\mu^{*} m^{*}$, and $b_{y t} \rightarrow b_{y}{ }^{*}=\mu^{*} m^{*} \beta^{*}=\frac{s_{B} \lambda(1-\alpha) e^{(r-g) H}}{1-s_{B} e^{(r-g) H}}$
Higher growth reduces inheritance: $\boldsymbol{\mu}^{\prime}(\mathrm{g})<0$
For reasonable parameter values, and low growth, inheritance ratios are very close to class saving levels: $\mu^{*}$ close to $\bar{\mu}$ and $b_{y}{ }^{*}$ close to $\beta^{*} / \mathbf{H}$

The generosity of the pension system ( $\rho \leq 1$ ) has a small impact on $b_{y}$

## Proposition 9 (wealth-in-the-utility model, open economy).

As $t \rightarrow+\infty, \mu_{\mathrm{t}} \rightarrow \mu^{*}=\mu(\mathrm{g}, \mathrm{r}), \mathrm{b}_{\mathrm{wt}} \rightarrow \mathrm{b}_{\mathrm{w}}{ }^{*}=\mu^{*} \mathrm{~m}^{*}$, and $\mathrm{b}_{\mathrm{yt}} \rightarrow \mathrm{b}_{\mathrm{y}}{ }^{*}=\mu^{*} \mathrm{~m}^{*} \beta^{*}=\frac{\mathrm{s}_{\mathrm{B}} \lambda(1-\alpha) \mathrm{e}^{(r-g) H}}{1-\mathrm{s}_{\mathrm{B}} \mathrm{e}^{(r-g) H}}$
Lower growth and/or higher rates of return raise inheritance: $\boldsymbol{\mu}^{\prime}(\mathbf{g})<\mathbf{0}, \boldsymbol{\mu}^{\prime}(\mathbf{r})>\mathbf{0}$.
With reasonable parameter values, and low growth and/or high rates of return, inheritance ratios are very close to class saving levels: $\mu^{*}$ close to $\bar{\mu}$ and $b_{y}{ }^{*}$ close to $\beta / \mathbf{H}$ The generosity of the pension system ( $\rho \leq 1$ ) has no impact on by.

So we obtain the same general results as with the exogenous saving model and the dynastic model. That is, steady-state inheritance ratios are a decreasing function of the growth rate and an increasing function of the rate or return; for low growth, they are almost exclusively determined by generation length H . Technically, one important difference is that the formulas for steady-state $\beta^{*}, r^{*}$ and $\mu^{*}$ are more complicated in the wealth-in-theutility model than in other models. In the closed economy case can be solved only by numerical methods. On the other hand the wealth-in-the-utility-function model implies a very simple closed-form formula for the steady-state inheritance flow $b_{y}$ *:

$$
\begin{equation*}
b_{y}{ }^{*}=b_{y}(g, r)=\frac{s_{\mathrm{B}} \lambda(1-\alpha) e^{(r-g) H}}{1-s_{\mathrm{B}} e^{(r-g) H}} \tag{5.15}
\end{equation*}
$$

This formula follows directly from the fact that agents devote a fraction $\mathrm{s}_{\mathrm{B}}$ of their lifetime resources (labor income and inherited wealth) to their end-of-life wealth. ${ }^{94}$ It holds both in the closed and open economy cases, and for any structure of intra-cohort labor income or

[^45]preference shocks. ${ }^{95}$ The intuition as to why the inheritance-income ratio $\mathrm{b}_{\mathrm{y}}{ }^{*}$ is a rising function of $r-g$ is straightforward. The excess of the rate of return over the growth rate exactly measures the extent to which wealth coming from the past is being capitalized at a faster pace than the growth rate of current income.

Numerical solutions to the theoretical formulas yield the following results. ${ }^{96}$ Assume $A=20$, $H=30, D=80, s_{B}=10 \%$, and $g=1 \%$. Then in the closed-economy case we get $r^{*}=4 \%$ and $b_{y}{ }^{*}=22 \%$. If life expectancy was instead $D=60$, we would get instead $b_{y}{ }^{*}=21 \%$. I.e. inheritance ratios are almost exclusively determined by generation length H , and depend very little on life expectancy. With $g=2 \%$, we get $r^{*}=5 \%$ and $b_{y}{ }^{*}=18 \%$ (both for $D=60$ and $D=80$ ). One needs to assume much larger growth rates to obtain more significant declines. In the open-economy case, inheritance can reach higher levels. E.g. with $D=80, s_{B}=10 \%$, $g=1 \%$ and $r=5 \%$, then $b_{y}{ }^{*}=30 \%$.

Also, note that in the closed-economy case, the generosity of pay-as-you-go pension system has a smaller impact than in the dynastic model (because crowding out is only partial, which seems more realistic). In the open-economy case, the generosity of the pay-as-you-go pension system has no impact at all: in effect, additional pension wealth is entirely invested abroad, so $b_{y}{ }^{*}$ is wholly unaffected. Though full international capital mobility is a somewhat extreme assumption, this result seems to capture a plausible intuition explaining why inherited wealth and pension wealth are to a large extent disconnected issues in today's global economy. That is, with high capital mobility, the fact that the generosity of pay-as-you-pension systems varies across countries should have little impact the magnitude of inheritance flows in the various countries.

[^46]
## 6. Simulations

We now come to the full fledged simulations. Our simulated model is conceptually simple. We start from observed demographic data. We also take as given observed nationalaccounts aggregate values for all macroeconomic variables (growth rates, factor shares, tax rates, rates of return, saving rates). We then make different assumptions about saving behaviour in order to see whether we can replicate observed age-wealth profiles, $\mu_{\mathrm{t}}$ ratios and the resulting inheritance flows.

More precisely, we constructed an exhaustive, annual demographic data base on the age structure of the living population and of decedents, heirs, donors and donees in France over the 1820-2008 period. In practice, bequest and gift flows accrue to individuals in several different payments during their lifetime: usually both parents do not die in the same year, sometime individuals receive gifts from their parents, and sometime they receive bequests and gifts from individuals other than their parents. We use the estate tax returns micro-files available since the 1970s (and the historical tabulations broken by decedent and donor age group available for the earlier period), as well as historical demographic data on age at parenthood, in order to compute the exact fraction of bequest and gift flow accruing to each cohort and transmitted by each cohort during each year of the 1820-2008 period. In the simulated model, the value of bequests is endogenous: it depends on the wealth at death of the relevant cohorts, as determined by the endogenous dynamics of the age-wealth profile. But the fraction of the aggregate bequest flow going to each cohort is taken from observed data. Regarding gifts, in some variants we take the observed giftbequet ratio $v_{t}$ as given, and in some other variants we assume other gift-bequest ratios (so as to check whether long run patterns are affected by $v_{t}$ ). In all variants, the age structure of donors and donees is exogenously given by our demographic data base.

Regarding the economic side of the model, we proceed as follows. We start from observed factor shares in national income, as measured by national accounts: $Y_{t}=Y_{k t}+Y_{\text {Lt }}$. We use national accounts tax and transfer series to compute aggregate, net-of-tax labor and pension income $\left(1-T_{L t}\right) Y_{L t}$ (where $T_{L t}$ is the aggregate labor tax rate, excluding pension payroll taxes). We use income tax data to estimate the age-labor income profile (including pension income) $Y_{\text {Lt }}(a)$ throughout the period, which we take as given. On this basis we attribute an average net-of-tax labor and pension income $y_{\text {Lt }}(a)$ to each cohort for each
year of the 1820-2008 period. Because we use liner saving models, we do not attempt to model intra-cohort inequality labor income or wealth.

We also take as given the average pre-tax rate of return $r_{t}$, which we compute by dividing capital income $\mathrm{Y}_{\mathrm{Kt}}$ by aggregate private wealth $\mathrm{W}_{\mathrm{t}}$, and the average after-tax rate of return $r_{d t}=\left(1-T_{K t}\right) r_{t}$ (where $T_{K t}$ is the aggregate capital tax rate). We assume that wealth holders from all age groups get the same average after-tax rate of return $r_{d t}$ on their wealth $W_{t}(a)$. This is very much a simplifying assumption. In the real world, rates of return vary widely across assets: typically, returns on stock and real estate are much larger than returns on bonds. ${ }^{97}$ This might possibly entail systematic differences across age groups. ${ }^{98}$ However we know very little on such systematic variations, so as a first approximation attributing the same average return to all age groups seems like the most reasonable assumption.

Our national-accounts approach to average rates of return $r_{t}$ and $r_{d t}$ also appears to be the most appropriate option. To the extent that national accounts correctly measure annual flows of capital income $Y_{K t}$ (rental income, interest, dividend, etc.), then $r_{t}$ and $r_{d t}$ indeed measure the true average rate of return received by holders of private wealth $W_{t}$ in France over the past two centuries. National accounts are not perfect. But this is arguably the most comprehensive data source we have, and one ought to start from there.

We present two main series of simulations: one for the 1820-1913 quasi-steady-state period, and one for the 1900-2008 U-shaped period (which was then extended to the future). In the first one, we start from the observed age-wealth profile in 1820, and attempt to simulate the evolution of the profile during the 1820-1913 period. In the second one, we start from the observed age-wealth profile in 1900, and attempt to simulate the evolution of the age-wealth profile during the 1900-2008 period. In both cases, the cohort level transition equation for wealth is the following: ${ }^{99}$

$$
\begin{equation*}
W_{t+1}(a+1)=\left(1+q_{t+1}\right)\left[W_{t}(a)+s_{L t} Y_{L t}(a)+s_{K t} r_{d t} W_{t}(a)\right] \tag{6.1}
\end{equation*}
$$

( + bequests and gifts received - bequests and gifts transmitted)

[^47]The real rates of capital gains $\mathrm{q}_{\mathrm{t}}$ come from our aggregate wealth accumulation equation. ${ }^{100}$ The only parameters on which we need to make assumptions are the laborincome and capital-income savings rates $s_{L t}$ and $s_{K t}$. We make various assumptions on these and analyze the extent to which we replicate observed age-wealth profiles, $\mu_{\mathrm{t}}$ ratios and resulting inheritance flows. In all simulations we make sure that the aggregate savings $s_{t}=\left(1-\alpha_{t}\right) s_{L t}+\alpha_{t} s_{k t}$ (where $\alpha_{t}$ is the observed, after-tax capital share) is equal to the observed private savings rate $\mathrm{s}_{\mathrm{t}}$, which according to national accounts data has been relatively stable around $8 \%-10 \%$ in France in the long run (see Figure 14).

By construction, the simulated model always perfectly reproduces the aggregate wealthincome ratio $\beta_{\mathrm{t}}=\mathrm{W}_{\mathrm{t}} / Y_{\mathrm{t}}$. The name of the game is the following: what assumptions on saving behaviour also allow us to reproduce the observed dynamics of age-wealth profiles, the $\mu_{\mathrm{t}}$ ratio and the inheritance flow-national income ratio byt?

Our main conclusion is summarized on Figures 15a-15b. By making simple assumptions on savings behaviour (namely, class saving for the 1820-1913 period, and uniform saving for the 1913-2008 period), we are able to reproduce remarkably well the observed evolution of the aggregate inheritance flow over almost two centuries. If we then use the model to predict the future, we find that the inheritance flow should stabilize or keep rising, depending on the future evolutions of growth rates and after-tax rates of return.

### 6.1. Simulating the 1820-1913 quasi-steady-state

The most interesting period to simulate and investigate is maybe the 1820-1913 period. As was already stressed, this is because this time period looks very close to the theoretical steady-state associated to the class saving model, with $s_{K}$ close to $\mathrm{g} / \mathrm{r}$, and $\mathrm{s}_{\mathrm{L}}$ close to 0 .

The first thing to notice is that the 1820-1913 period was a time when the rate of return to private wealth $r$ was much bigger than the growth rate $g$. Generally speaking, factor shares appear to have been relatively stable in France over the past two centuries, with a capital share generally around $30 \%$ (see Figure 16). Note however that according to the best available data, the capital share during the $19^{\text {th }}$ century was somewhat higher than during the $20^{\text {th }}$ century ( $30 \%-40 \%$, vs $20 \%-30 \%$ ). Dividing capital shares by aggregate wealth-

[^48]income ratios, we get average rates of returns to private wealth $r_{t}$ of about $5 \%-6 \%$ in 18201913, much larger than the growth rate, which on average was only $1.0 \%$ (see Figure 17).

We run several simulations. If we assume uniform saving rates, then we under-predict somewhat the aggregate evolution of inheritance. Most importantly, we predict an agewealth profile in 1900-1910 that is flat after age 60 (or even slightly declining after age 70), while the observed profile is steeply increasing, including for the very old. This has a limited impact on the aggregate $\mu_{\mathrm{t}}$ and byt ratios, because at that time few people died after age 70. But this is an important part of the observed data. This shows that uniform saving is an inadequate description of actual savings behaviour at that time. If we assume that all savings came from capital income, which implies $\mathrm{s}_{\mathrm{K}} \approx 25 \%-30 \%$ and $\mathrm{s}_{\mathrm{L}} \approx 0 \%$ (instead of $\left.\mathrm{s}_{\mathrm{K}}=\mathrm{s}_{\mathrm{L}} \approx 8 \%-10 \%\right)$, then we can predict adequately both the evolution of the inheritanceincome ratio $b_{y t}$ and the evolution of the age-wealth profiles $w_{t}(a)$.

Given the very large wealth concentration prevailing at that time, class saving behavior seems highly plausible. The income levels and living standards attained by wealth holders were so much higher than those of the rest of the population that is was not too difficult for them to save $25 \%-30 \%$ of their capital income annually. In order to fully account for the steepness of the age-wealth profile around 1900-1910, one would actually need to assume not only that (most) savings come from capital income, but also that the average saving rate $\mathrm{s}_{\mathrm{K}}(\mathrm{a})$ actually rises with age. This could be explained by a simple consumption satiation effect among elderly wealth holders. To properly study this issue, one would need however to explicitly introduce distributional issues and to use micro data.

We also did various sensitivity checks by varying the gift-bequest ratio $\mathrm{v}_{\mathrm{t}}$. In particular, in one variant, we set $\mathrm{v}_{\mathrm{t}}=0 \%$ for the entire 1820-1913 period, i.e. $19^{\text {th }}$ century wealth holders were assumed to make no inter vivos gifts and to hold on their wealth until the die. Of course, this leads us to under-predict the observed inheritance (bequests plus gifts) flow at the beginning of the period. The interesting finding, however, is that we get approximately the same inheritance-income ratio at the end of the period (about 20\%) than the observed ratio with gifts (but with an even more steeply increasing age-wealth profile). This validates our methodological choice of adding gifts to bequests. The existence of inter-vivos gifts has an impact on the timing of inheritance receipts, but very little impact on the long run aggregate flow of aggregate wealth transmission.

### 6.2. Simulating the $20^{\text {th }}$ century chaotic U-shaped pattern

We proceed in the same way for the $20^{\text {th }}$ century. Whether we assume uniform savings or class savings, the model predicts a decline in the $\mu_{\mathrm{t}}$ ratio during the 1913-1949 period. The channel through which this effect operates is the one that we already described, i.e. it was too late for the elderly to start re-accumulating wealth again after the shocks. However we get a significantly better fit by assuming that aggregate savings behaviour has shifted from class savings to uniform savings during the 1913-1949 period. For instance, if we look at the inheritance-income ratio at its lowest point, i.e. during the 1950s (4.3\%), we predict $5.3 \%$ with uniform saving and $6.0 \%$ with class saving.

Intuitively, this structural change in saving behaviour could come from the large decline in wealth concentration that occurred during that time: top wealth holders were much less prosperous than they used to be, and they were not able to save as much. It could even be that they saved even less than labor earners, for instance if they tried to maintain their living standards for too long. The other possible interpretation as to why we slightly over predict the observed 1950s inheritance flow (even with uniform saving) is because the capital shocks of the 1913-1949 disproportionally hit elderly wealth holders, e.g. because they held a larger fraction of their wealth in bonds and other nominal assets. In the simulated model, we assume that the shocks (both the destruction shocks and the capital losses) hit all wealth holders in a proportional manner. Finally, it is possible that the gradual rise in age expectancy that occurred during this period led to a rise in lifecycle savings out of labor income. The data we use in this paper is insufficient to settle this issue. Our aggregate approach allows us to adequately reproduce the general pattern over a two century period. But in order to better understand the micro processes at work, one would clearly need to model explicitly distributional issues and to use micro data.

The post 1949 simulations confirm the view that a structural shift from class saving to uniform saving occurred during the $20^{\text {th }}$ century. All saving models predict a strong recovery of $\mu_{\mathrm{t}}$ and byt between the 1950s and the 2000s (especially since the 1970s, due to lower growth rates, see below). But class saving would lead us to over predict the recovery, with an inheritance flow of $16.8 \%$ in 2010 , vs $14.4 \%$ with uniform savings, vs $13.8 \%$ with reverse class savings (i.e. zero saving from capital income), vs $14.5 \%$ in the observed data. We interpret this as evidence in favour of the uniform saving assumption as an adequate way to describe postwar aggregate savings behaviour (as a first
approximation). This interpretation seems to be consistent with micro evidence from French household budget surveys: aggregate age-saving rates profiles have been quasiflat during the 1978-2006 period, and do not appear to vary systematically with factor income composition. ${ }^{101}$ This is imperfect data, however, and this issue would need to be better addressed in future research, by introducing explicitly distributional effects.

The simulations as a whole also confirm the critical importance of the r>g logic. Also, as predicted by the theoretical formulas, the absolute level of $g$ appears to have a stronger quantitative impact than the differential r-g. This is exemplified by the 1949-1979 period. Growth rates were above $5 \%$, which slowed down considerably the rise of the $\mu_{\mathrm{t}}$ ratio. During the 1979-2009 period, growth slowed down to $1 \%-2 \%$, the rise of the $\mu_{\mathrm{t}}$ ratio was more rapid, and so was the recovery of the inheritance-income ratio $\mathrm{b}_{\mathrm{yt}}$. This simple growth effect plays a much bigger role than saving behaviour, as predicted by the theory.

Finally, capital taxes play an important role in our simulations. The average rate of return on private wealth $r_{t}=\alpha_{t} / \beta_{t}$ has always been much larger than the growth rate $g_{t}$ in France, both during the $19^{\text {th }}$ and the $20^{\text {th }}$ centuries (see Table 3 ). The major change is that the effective capital tax rate $T_{K t}$ was less than $10 \%$ prior to World War 1 , then rose to about $20 \%$ in the interwar period, and finally grew to $30 \%-40 \%$ in the postwar period. ${ }^{102}$ This had a large impact on the differential between $r_{d t}=\left(1-T_{K t}\right) r_{t}$ and $g_{t}$. In particular, capital taxes largely explain why the differential was relatively small (but still positive) during the 19491979 period, in spite of positive capital gains. In our simulations, this differential has a smaller impact on $\mu_{\mathrm{t}}$ and $\mathrm{b}_{\mathrm{yt}}$ than the absolute growth rate level, but the effect is still significant. We further investigate this issue with $21^{\text {st }}$ century simulations.

### 6.3. Simulating the $21^{\text {st }}$ century: towards a new steady-state?

In our baseline scenario, we assume that growth rates in 2010-2100 will be the same as the 1979-2009 average (1.7\%), that the aggregate saving rate will be the same as the

[^49]1979-2009 average (9.4\%), and that the capital share will be the same as the 2008 value $(26 \%) .{ }^{103}$ On the basis of the historical evolutions described in section 3.2 above, we assume that asset prices remain the same (relatively to consumer prices) after 2010.

In this scenario, we predict that the inheritance-income ratio byt will keep increasing somewhat after 2010, but will soon stabilize at about $16 \%$ (see Figure 15a). There are several reasons why this new steady-state level is substantially below the 20\%-25\% quasi-steady-state level prevailing in 1820-1913. First, our projected growth rate (1.7\%) is small, but bigger than the $19^{\text {th }}$ century growth rate (1.0\%). Next, our projected after-tax rate of return $(3.0 \%)$ is substantially smaller than the $19^{\text {th }}$ century level ( $5.3 \%$ ).

We then consider an alternative scenario with a growth slowdown after 2010 (1.0\%), and a rise of the after-tax rate of return to $5.0 \%$. This could be due either to a large rise in the capital share (say, because of increased international competition to attract capital), or to a complete elimination of capital taxes (which could also be triggered by international competition), or to a combination of the two. Under these assumptions, the inheritanceincome ratio converges towards a new steady-state around $22 \%-23 \%$ by $2050-2060$, i.e. approximately the same level as that prevailing in the early $20^{\text {th }}$ century (see Figure 15 b).

This finding confirms that the rise in life expectancy has little effect on the long run level of inheritance. With low growth and high returns, the inheritance-income ratio depends almost exclusively on generation length H . Detailed results also show that the largest part of the effect (about two thirds) comes from the growth slowdown, versus about one third for the rise in the net-of-tax rate of return. This decomposition is relatively sensitive to assumptions about savings behaviour, however.

We also explored various alternative scenarios. With a 5\% growth rate after 2010, and a rise in saving rate to $25 \%$, so as to preserve a plausible aggregate wealth income ratio, inheritance flows converge towards about 12\% of national income by 2050-2060. With no rise in savings, inheritance flows converge to about $5 \%-6 \%$ of national income (i.e. approximately the same level as in the 1950s-1960s). But this is largely due to the fall in the aggregate wealth-income ratio. Another equivalent scenario would involve large scale capital shocks similar to the 1913-1949 period, with capital destructions, and/or a

[^50]prolonged fall in asset prices, due to rent control, nationalization, high capital taxes or other anti-capital policies. Given the chaotic $20^{\text {th }}$ century record, one certainly cannot exclude such a radical scenario. The bottom line, however, is that a return to the exceptionally low inheritance flows of the 1950s-1960s can occur only under fairly extreme assumptions. One needs a combination of exceptionally high growth rates during several decades and a large fall in aggregate wealth-income ratio.

Finally, we made simulations assuming that the gift-bequest ratio $v_{t}$ did not rise after 1980. This is an important sensitivity check, because the large rise in gifts in recent decades played an important role in the overall analysis. We find a predicted inheritance-income ratio of $15 \%$ by 2050 , instead of $16 \%$ in the baseline scenario. This suggests that the current gift levels are almost fully sustainable. We also simulated the entire 1900-2100 period assuming there was no gift at all. In the same way as for the 1820-1913 period, this has little effect on long run patterns, which again validates the way we treated gifts.

## 7. Applications \& directions for future research

### 7.1. The share of inheritance in total lifetime resources by cohort

In this paper, we mostly focused on the cross-sectional inheritance flow-national income ratio $b_{y t}=B_{t} / Y_{t}$. However this ratio is closely related to another ratio: namely the share of inheritance in the lifetime resources of the currently inheriting cohort, which we note $\hat{\alpha}_{t}$.

To see why, consider again the deterministic, stationary demographic structure introduced in section 5. Everybody becomes adult at age A, has one kid at age H, inherits at age $\mathrm{I}=\mathrm{D}-\mathrm{H}$, and dies at age D . Each cohort size is normalized to 1, so that total (adult) population $N_{t}$ is equal to (adult) life length $D-A$. Per decedent inheritance $b_{t}=B_{t}=b_{y t} Y_{t}$ and per adult income $y_{t}=Y_{t} /(D-A)$. At time $t$, the cohort receiving average inheritance $b_{t}$ is the cohort born at time $x=t-I$. We note $\tilde{y}_{t}=\tilde{b}_{t}+\tilde{y}_{L t}$ the total lifetime resources received by cohort x , where $\tilde{\mathrm{b}}_{\mathrm{t}}=\mathrm{b}_{\mathrm{t}} \mathrm{e}^{\mathrm{rH}}$ is the end-of-life capitalized value of their inheritance resources, and $\tilde{y}_{\mathrm{Lt}}$ is the end-of-life capitalized value of their labor income resources. We define $\hat{\alpha}_{t}=\tilde{b}_{t} / \tilde{y}_{t}$ the share of inheritance in total lifetime resources of this cohort. Assuming flat age-labor income profile $y_{L t}(a)=y_{L t}$ (i.e. full replacement rate $\rho=1$ ), we have:

$$
\begin{gather*}
\tilde{y}_{L t}=\int_{A \leq a \leq D} e^{r(D-a)} y_{L}{ }^{x}(a) d a=\int_{A \leq a \leq D} e^{r(D-a)} y_{L t} e^{g(a-1)} d a \\
\text { I.e. } \tilde{y}_{L t}=\lambda(D-A) y_{L t} e^{r H}=\lambda Y_{L t} e^{r H}=\lambda(1-a) Y_{t} e^{r H} \\
\text { With: } \quad \lambda=\frac{e^{(r-g)(l-A)}-e^{-(r-g)(D-1)}}{(r-g)(D-A)} \tag{7.1}
\end{gather*}
$$

We therefore have a simple formula for $\hat{\alpha}_{t}$ as a function of $b_{y t}$ :

Proposition 10. Define $\hat{\alpha}_{t}$ the share of inheritance in the total lifetime resources of the cohort inheriting at time $t$. Then we have: $\hat{\alpha}_{t}=\frac{b_{y t}}{b_{y t}+\lambda(1-\alpha)}$

With: $b_{y t}=$ inheritance flow-national income ratio
$1-\alpha=$ labor share in national income
$\lambda=$ correcting factor given by equation (7.1)

The inheritance share $\hat{\alpha}_{t}$ can be viewed as an indicator of the functional distribution of resources accruing to individuals. During their lifetime, individuals from cohort $x$ receive on average a fraction $\hat{\alpha}_{t}$ of their resources through inheritance, and a fraction 1- $\hat{\alpha}_{t}$ through their labor income. $\hat{a}_{t}$ is simply related to the standard cross-sectional capital share $\alpha$. If $\lambda \approx 1$, which as we see below is typically the case, then $\hat{\alpha}_{t}>\alpha$ iff $b_{y t}>\alpha$. That is, the share of inheritance in lifetime resources is larger than the capital share in national income if and only if the inheritance flow is larger than the capital share. In general, both cases can happen: there are societies where the capital share is large but the inheritance share is low (say, because most wealth comes from lifecycle accumulation), and conversely there are societies where the inheritance is large but where the capital share is low (say, because capital serves mostly as storage of value and produces little flow returns).

It is interesting to see that in practice the inheritance share $\hat{\alpha}$ and the capital share $\alpha$ happen to have the same order of magnitude (typically around $20 \%-30 \%$ ) - mostly by coincidence, as far as we can see. Proposition 10 is pure accounting, and it holds for any saving model, both in and out of steady-state (one simply needs to use time-varying $g_{t}$ and $r_{t}$ to compute $\lambda$ ). If we now apply Proposition 10 to the steady-state models analyzed in section 5, then we just need to replace $b_{y t}$ by the relevant steady-state value $b_{y}$. So for instance in the class saving model or in the dynastic model, we have $b_{y}=\beta / H$, so that:

$$
\begin{equation*}
\hat{\alpha}=\frac{b_{y}}{b_{y}+\lambda(1-\alpha)}=\frac{\beta}{\beta+\lambda(1-\alpha) H} \tag{7.3}
\end{equation*}
$$

Example. With benchmark values $\beta=600 \%, H=30, \alpha=30 \%, \lambda=1$, we have $b_{y}=20 \%$, and $\hat{\alpha}=b_{y} /\left(b_{y}+1-\alpha\right)=22 \%$. That is, in steady-state each cohort derives $\hat{\alpha}=22 \%$ of its lifetime resources through inheritance, and $1-\hat{\alpha}=78 \%$ through labor. To put it differently, inheritance resources represents $\psi=b_{y} /(1-\alpha)=29 \%$ of their labor resources.

We now come to the correcting factor $\lambda$. Intuitively, $\lambda$ corrects for differences between the lifetime profile of labor income flows and the lifetime profile of inheritance flows. That is, $\lambda$ measures the relative capitalized value of $1 €$ in labor resources vs $1 €$ in inheritance resources, given the differences in lifetime profile between both flows of resources.

In the stylized model with deterministic demographic structure, all inheritance flows come at age $a=l$, while labor income flows come from age $a=A$ until age $a=D$. The flows received before age $\mathrm{a}=\mathrm{I}$ are smaller in size but needs to be capitalized; the flows received after age $a=I$ are larger in size but needs to be discounted. In case $r-g=0 \%$, then the growth and capitalization effects cancel each other, so $\lambda$ is exactly equal to $100 \%$. Simple first order approximations using the $\lambda$ formula (equation (7.1) above) also show that if inheritance happens around mid-life (say, $A=20, H=30, D=80, I=D-H=50$ ), then $\lambda$ will tend to be close to $100 \%$ even if $r-g>0 .{ }^{104}$ When inheritance happens early in adult life (say, $A=20, H=30$, $D=80$, $I=D-H=30$ ), then $\lambda$ is below $100 \%$. Flows of resources accruing earlier in life are worth more from a lifetime, capitalized value perspective. Since inheritance flows were received relatively earlier in life one century ago, this effect implies that - other things equal - the relative importance of labour income should have increased over time.

Example. Assume $r-g=3 \%$ (say, $g=2 \%, r=5 \%$ ). With $A=20, H=30, D=80$, then $\lambda=114 \%$. With $A=20, H=30, D=60$, then $\lambda=79 \% .{ }^{105}$

In practice, however, there are several other counteracting effects. In the real world, individuals receive bequests and inter vivos gifts at different point in their life (and not only at age $\mathrm{a}=\mathrm{I}$ ), and the gift-bequest ratio has risen over time. Also the cross-sectional agelabor income profile is not flat: young and old individuals receive smaller average labor income and middle age individuals.

So we use our simulated model, based upon observed and simulated data on the complete age profiles of bequest, gift and labor income receipts, in order to compute the correcting factor $\lambda^{x}$ for all cohorts born in France between $x=1800$ and $x=2030$. We find that $\lambda^{x}$ has been remarkably constant around $90 \%-110 \%$ over two centuries, with no long run trend. Since we observe bequest and gift flows until 2008, the latest cohorts for which we have complete (or near complete) observed data are those born in 1950s-1960s, for whom the $\lambda^{\times}$factor is about $100 \%-110 \%$. For cohorts born in the 1970s and later, our computations increasingly rely on our simulations on future inheritance flows, i.e. on our assumptions about 2010-2100 growth rates and rates of return. Under the benchmark scenario ( $g=1.7 \%$, $\left(1-\mathrm{T}_{\mathrm{K}}\right) \mathrm{r}=3.0 \%$ ), we find that $\lambda^{\mathrm{x}}$ will be stable around $100 \%-110 \%$ for

[^51]cohorts 1970-2030. Under the growth slowdown-rising wealth returns scenario ( $\mathrm{g}=1.0 \%$, $\left(1-T_{K}\right) r=5.0 \%$ ), we find that $\lambda^{x}$ will be rising to about $110 \%-120 \%$ for cohorts 1970-2030. ${ }^{106}$

We also use our simulated model in order to compute the capitalized value of lifetime resources $\widetilde{y}^{x}=\tilde{b}^{x}+\tilde{y}_{L}{ }^{x}$ for all French cohorts born between $x=1800$ and $x=2030$. Unsurprisingly, we find that the inheritance share in lifetime resources $\hat{\mathrm{a}}^{x}=\tilde{\mathrm{b}}^{\mathrm{x}} / \tilde{\mathrm{y}}^{x}$ has been following a marked U-shaped pattern: $\hat{\alpha}^{\mathrm{x}}$ was about $20 \%-25 \%$ for $19^{\text {th }}$ century cohorts, fell to less than $10 \%$ for cohorts born in the 1900s-1930s, then gradually rose to $15 \%-20 \%$ for cohorts born in the 1950s-1960s, and is expected to stabilitize around $20 \%-25 \%$ for cohorts 1970-2030 (benchmark scenario). If we instead plot the ratio $\psi^{x}=\tilde{b}^{x} / \tilde{y}_{L}{ }^{x}$ between average inheritance resources and average labor resources $\left(\Psi^{\mathrm{x}}=\hat{\alpha}^{\mathrm{x}} /\left(1-\hat{\alpha}^{\mathrm{x}}\right)\right)$, then all levels are simply shifted upwards. I.e. $19^{\text {th }}$ century cohorts received in inheritance the equivalent of about $30 \%$ of their lifetime labor income; this figure declined to about $12 \%$ for cohorts 1900-1930, and is projected to be about 30\% for cohorts 1970-2030 (see Figure 19a).

Here it might be useful to give some orders of magnitude. Consider the cohorts born in the 1960s, who have already received a large fraction of their gifts and bequests in the 1990s2000s. We find that their average lifetime resources, capitalized at age 50 (in the 2010s), are about 1.78 millions $€$, out of which about $320,000 €$ come from inheritance, and about 1.46 millions $€$ come from labor income. ${ }^{107}$ So we have: $\hat{\alpha}^{x}=18 \%$ and $\psi^{x}=22 \%$. Given that $\lambda$ is close to 1 , these average labor income resources roughly correspond to the product of average per adult labor income (currently about $25,000 €$ in France) by average adult life length (about 60 years). With the cohorts born in the 1970s, we find 2.02 millions $€$, $440,000 €$ and 1.58 millions $€$. So $\hat{\alpha}^{x}=22 \%$ and $\Psi^{x}=28 \%$. On Figure 19a we therefore plot $\psi^{\mathrm{x}}=22 \%$ for the 1960s and $\psi^{\mathrm{x}}=28 \%$ for the 1970s.

As predicted by the simplified theoretical model (Proposition 10), the historical evolution of the cohort-level inheritance-labor income ratio $\psi^{x}$ (Figure 19a) is the mirror image of the pattern found for the cross-sectional inheritance flow-national income ratio $b_{y t}$ (Figure 15a). There are two interesting differences, however.

[^52]First, the U-shaped pattern is less marked for $\psi^{\mathrm{x}}$ than for $\mathrm{b}_{\mathrm{y} \text { t. }}$ At its lowest point, i.e. in the 1950s, the inheritance flow byt was less than $5 \%$ of national income. In comparison, the lowest point of $\Psi^{\times}$, which was attained for cohorts born in the 1900s-1930s, is somewhat above $10 \%$. This is because all members of a given cohort do not inherit exactly at the same time. E.g. cohorts born in the 1900s-1930s inherited everywhere between the 1940s and 1970s. So when we compute cohort level averages of inheritance resources, we tend to smooth cross-sectional evolutions of the inheritance flow-national income ratio. The cohort level pattern is nevertheless quite spectacular. Cohorts born in the $19^{\text {th }}$ century were used to receive by inheritance the equivalent of about $30 \%$ of their lifetime labor income. This figure suddenly fell to little more than $10 \%$ for cohorts born in the 1900s1930s, and it took several decades before returning to $19^{\text {th }}$ century levels. The point is that cohorts born in the 1900s-1930s (and to a lesser extent those born in the 1940s-1950s) had to rely mostly on themselves in order to accumulate wealth. Maybe it is not too surprising if they happen to be strong believers in lifecycle theory.

Next, it is striking to see that in our benchmark simulations $\hat{\alpha}^{x}$ and $\psi^{x}$ attain approximately the same levels for cohorts born in the 1970s and after as for $19^{\text {th }}$ century cohorts ( $\hat{\alpha}^{\times} \approx 20 \%-25 \%, \psi^{\times} \approx 30 \%$ ), in spite of the fact that we project $b_{y t}$ to stabilize below $19^{\text {th }}$ century levels ( $15 \%-16 \%$ instead of $20 \%-25 \%$ ). This is due to a differential tax effect. $\hat{\alpha}^{x}$ and $\Psi^{\times}$were computed from the simulated model, which uses observed after-tax resources, so these are effectively after-tax ratios. The aggregate labor income tax rate $\mathrm{T}_{\mathrm{L}}$ rose from less than $10 \%$ in the $19^{\text {th }}$ century-early $20^{\text {th }}$ century to about $30 \%$ in the late $20^{\text {th }}$ century-early $21^{\text {st }}$ century. ${ }^{108}$ The aggregate inheritance tax rate has remained relatively small throughout the $19^{\text {th }}-20^{\text {th }}$ centuries (about $5 \%$, with no trend). ${ }^{109}$ This mechanically raises the after-tax value of inheritance resources relatively to labor resources. Since modern fiscal systems tax labor much more heavily than inherited wealth, the inheritance flow-national income ratio does not need to be as large as during the $19^{\text {th }}$ century in order to generate the same share of inheritance in disposable lifetime resources. ${ }^{110}$

[^53]For illustrative purposes, we did the same computations with the growth slowdown-rising wealth returns scenario ( $\left.g=1.0 \%,\left(1-T_{K}\right) r=5.0 \%\right)$, under which $b_{y t}$ is projected to return to the $19^{\text {th }}$ century levels (see Figure 15b). Because of the differential tax effect, we project that $\hat{\alpha}^{\mathrm{x}}$ will be about $25 \%-30 \%$ for cohorts born in the 1970 s-1980s, and as large as $35 \%-$ 40\% for cohorts born in the 2010s-2020s, which corresponds to an inheritance-labor ratio $\psi^{\times}$over $60 \% .{ }^{111}$ That is, we project that cohorts born in the coming years will receive in inheritance the equivalent of over $60 \%$ of what they will receive in labor income during their entire lifetime, far above $19^{\text {th }}$ century levels (see Figure 19b). This shows that taxes can have a strong impact on the balance between inheritance and labor resources.

### 7.2. Labor-based vs inheritance-based inequality

Now that we have computed the inheritance share in average lifetime resources, we are in a position to put inequality back into the picture. Our objective is to illustrate that changes in aggregate ratios $\hat{\alpha}^{\times}$and $\psi^{x}$ matter a great deal for the study of inequality. We do this by making simple assumptions about the intra-cohort distributions of labor income and inheritance, taken from the recent literature on top income and top wealth shares.

Our distributional assumptions are summarized on Table 4. The inequality of labor income has been relatively stable in France throughout the $20^{\text {th }}$ century. So we assume constant shares for the bottom $50 \%$, the middle $40 \%$, and the top $10 \%$ of the intra-cohort distribution of labor income for all cohorts born in 1820-2020. Wealth concentration has always been much larger than that of labor income. It was particularly high during the 1820-1913 period, when the top 10\% (the "upper class") owned over $90 \%$ of aggregate wealth, with little left for the middle $40 \%$ (the "middle class") and the bottom $50 \%$ (the "poor"). Basically, there was no middle class. Today, the poor still own less than $5 \%$ of aggregate wealth. But the middle class share rose from $5 \%$ to $35 \%$, while the upper class share dropped from $90 \%$ to $60 \%$. Wealth concentration declined mostly during the 19141945 period, and seems to have stabilized since the 1950s-1960s (as a first approximation). ${ }^{112}$ For simplicity, we apply 1910 inherited wealth shares by fractiles to all cohorts born in 1820-1870, we apply 2010 shares to all cohorts born in 1920-2020, and we assume linear changes in shares for cohorts born between 1870 and 1920.

[^54]By applying these assumptions to the lifetime inheritance-labor income resources ratio $\psi^{x}$ plotted on Figure 19a, we obtain the inequality indicators plotted on Figures 20a-23a (benchmark scenario). Consider first the ratio between the lifetime resources available for the top $50 \%$ successors and those available for the bottom $50 \%$ labor earners. Since the top $50 \%$ wealth share has been stable at $95 \%$, and the bottom $50 \%$ labor income share has been stable $30 \%$, this ratio follows exactly the same U-shaped pattern as the aggregate $\psi^{\mathrm{x}}$, with levels multiplied by about three. In the $19^{\text {th }}$ century, the top $50 \%$ successors received in inheritance about 100\% of what the bottom 50\% labor earners received in labor income throughout their lifetime. Then this ratio dropped to $30 \%-40 \%$ for cohorts born in the 1900s-1930s. According to our computations, this ratio has now well recovered, and is be about $90 \%$ for cohorts born in the 1970s-1980s (see Figure 20a).

Take again the example of the cohorts born in the 1970s. On average they will receive $440,000 €$ in inheritance. But the bottom half will receive almost no inheritance $(40,000 €)$, while the upper half will receive almost twice this amount $(840,000 €)$. This is roughly what the bottom $50 \%$ labor earners will receive in labor income ( $950,000 €$ ). So we get the ratio of $88 \%$ plotted for the 1970s on Figure 20a. On average, the bottom $50 \%$ labor earners earn little more than the minimum wage: their lifetime labor income roughly corresponds to the product of about $15,000 €$ by adult life length (about 60 years). For the sake of concreteness they can be thought of as minimum wage workers.

Consider now the ratios between what top $10 \%$ and top $1 \%$ successors receive in inheritance and what minimum wage workers receive in labor income. Due to the decline in wealth concentration, these inequality indicators are still lower for current generations than what they used to be in the $19^{\text {th }}$ century. But they are much higher than what they used for cohorts born in 1900-1940, in spite of the fact that intra cohort distributions have remained the same. This illustrates the importance of changes in the aggregate ratio $\psi^{\times}$.

For cohorts born between the 1900s and the 1950s, it was almost impossible to become rich through inheritance. Even if you belong to the top $10 \%$ or top $1 \%$ successors, or if you marry with such a person, the corresponding lifetime resources would be a lot smaller than those you can attain by making your way to the top $10 \%$ or top $1 \%$ of the labor income hierarchy of your time (see Figures 21a-22a). This is what most people would describe as
a "meritocratic society". Material well-being required high labor income. For the first time maybe in history, it was difficult to live as well by simply receiving inheritance.

In the $19^{\text {th }}$ century, the world looked very different. Top $10 \%$ inheritance resources were roughly equivalent to top $10 \%$ labor resources. Top $1 \%$ inheritance resources were almost three times as large as top $1 \%$ labor resources. I.e. top rentiers vastly dominated top labor earners. If you want to attain high living standards in the $19^{\text {th }}$ century, then inheriting from your parents or your spouse's family is a much better strategy than work. This looks very much like a "rentier society".

Life opportunities open to today's generations are intermediate between the meritocratic society of the 1900-1950 cohorts and the rentier society of the $19^{\text {th }}$ century. For cohorts born in the 1970s, we find that the lifetime resources attained by the $1 \%$ successors and top $1 \%$ labor earners will be roughly equivalent. I.e. finding a top $1 \%$ job or a top $1 \%$ spouse will get you to the same living standards: you obtain about 10 millions $€$ in both cases (see Table 5). In the $19^{\text {th }}$ century, the spouse strategy was three times more profitable. For early $20^{\text {th }}$ century cohorts, the job strategy was twice more profitable.

The decline in wealth concentration makes it less likely to inherit sufficiently large amounts to sustain high living standards with zero labor income. But it makes it more likely - for a given aggregate inheritance-labor ratio $\psi^{\mathrm{x}}$ - to receive amounts which are not enough to be a rentier, but which still make a big difference in life, at least as compared to what most people earn. Using standard Pareto assumptions on the shape of the intra cohort distribution of inherited wealth, we find that the cohort fraction inheriting more than minimum wage lifetime income (about $950,000 €$ for 1970s cohorts) was less than $10 \%$ in the $19^{\text {th }}$ century, and will be as large as $12 \%-14 \%$ for cohorts born in the 1970 s-2000s. Among cohorts born in the 1900s-1930s, this almost never happened: only $2 \%-3 \%$ of each cohort inherited that much (see Figure 23a).

We did the same computations under the low-growth, high-return scenario (see Figures 20b-23b). Unsurprisingly, given that we project the aggregate inheritance-labor ratio $\psi^{\mathrm{x}}$ to rise well above $19^{\text {th }}$ century values, we also find that our lifetime inequality indicators reach unheard of levels. At the top $1 \%$ level, the spouse strategy again becomes almost three times more profitable: the aggregate effect entirely compensates the distribution effect.

These computations should be viewed as illustrative and exploratory. They ought to be improved in many ways. First, progressive taxation of inheritance and labor income can obviously have a strong impact on such inequality indicators, both in the short run (mechanical effect) and in the long run (endogenous intra-cohort distribution effect). Here we ignored progressive taxes altogether. I.e. in our aggregate computations we simply assumed that inheritance and labor income taxes were purely proportional.

Next, we made no assumption about the individual-level rank correlation between the intra-cohort distributions of inheritance and labor income. Our inequality indicators hold for any joint distribution $\mathrm{G}\left(\tilde{\mathrm{b}}_{\mathrm{i}}{ }^{\mathrm{X}}, \tilde{\mathrm{y}}_{\mathrm{Li}}{ }^{\mathrm{x}}\right)$. In practice, $\operatorname{corr}\left(\widetilde{\mathrm{b}}_{\mathrm{i}}{ }^{\mathrm{X}}, \tilde{\mathrm{y}}_{\mathrm{Li}}{ }^{\mathrm{x}}\right)$ might be endogenous. With publicly financed education and the lessening of credit constraints, one might expect the correlation to decline over time. But this could be counterbalanced by the fact that top heirs now need to work in order to reach the same relative living standards as in the past. So the correlation might have increased. It could also be that the moral value attached to work has risen somewhat, so that top successors work more than they used to. Or maybe they have always worked. We do not know of any evidence on this interesting issue.

Finally, we looked at a country with a relatively stable distribution of labor income. So for simplicity we assumed full stability, including at the top. In practice, the top 1\% share actually rose a little bit in France in the late 1990s-early 2000s (from about 6\% to 7\%-8\% of aggregate labor income). This is too small a trend to make a significant difference so far. But if we were to make the same computations for the U.S., where the top $1 \%$ share rose from $6 \%-7 \%$ in the 1970 s to $15 \%-20 \%$ in the 2000 s, this would have strong and contradictory impacts on our inheritance-labor inequality indicators. The rise of the working rich reduces the inequality between top successors and top labor earners. But it increases the inequality between the working poor and successors as a whole. It also has dynamic effects on the future intra-cohort distributions of inherited wealth.

### 7.3. The share of inheritance in aggregate wealth accumulation

The inheritance flow-national income ratio $\mathrm{b}_{\mathrm{yt}}=\mathrm{B}_{\mathrm{t}} / Y_{\mathrm{t}}$ analyzed in this paper is also closely related to the share of inheritance in aggregate wealth accumulation, which we note $\varphi_{t}$.

There are two competing definitions of $\varphi_{t}$ in the economics literature. Modigliani (1986, 1988) define $\varphi_{t}{ }^{M}$ as the share of non-capitalized past bequests in total wealth, while Kotlikoff and Summers $(1981,1988)$ use the share of capitalized past bequests $\varphi_{t}{ }^{\text {Ks }}$ :

$$
\begin{gather*}
\varphi_{t}^{\mathrm{M}}=\hat{B}_{t} / W_{t} \text {, with: } \hat{B}_{t}=\int_{s \leq t} \quad B_{s t} d s  \tag{7.4}\\
\varphi_{t}^{K s}=\widetilde{B}_{t} / W_{t} \text {, with: } \widetilde{B}_{t}=\int_{s \leq t} \quad B_{s t} e^{r_{s t}} d s \tag{7.5}
\end{gather*}
$$

With: $B_{\text {st }}=$ aggregate bequests received at time $s$ by individuals who are still alive at time $t$ $r_{s t}=$ cumulated return to wealth between time s and time $t$

Consider again the deterministic, stationary demographic structure introduced in section 5 . Everybody becomes adult at age A, has one kid at age H, inherits at age I=D-H, and dies at age $D$. Each cohort size is normalized to 1 , so that total (adult) population $N_{t}$ is equal to life length D-A. Along a steady-state path with constant growth rate g , rate of return r , wealth-income ratio $\beta=W_{t} / Y_{t}$ and inheritance flow-income ratio $b_{y}=B_{t} / Y_{t}$, we have: ${ }^{113}$

$$
\begin{align*}
& \varphi_{t}^{M}=\int_{t-H \leq s \leq t} \frac{b_{y}}{\beta} e^{-g(t-s)} d s=\frac{b_{y}}{\beta} \frac{1-e^{-g H}}{g}  \tag{7.6}\\
& \varphi_{t}^{K s}=\int_{t-H \leq s \leq t} \frac{b_{y}}{\beta} e^{(r-g)(t-s)} d s=\frac{b_{y}}{\beta} \frac{e^{(r-g) H}-1}{r-g} \tag{7.7}
\end{align*}
$$

Proposition 11. Define $\varphi_{t}{ }^{M}$ the non-capitalized bequest share in aggregate wealth and $\varphi_{t}{ }^{\mathrm{KS}}$ the capitalized bequest share. In steady-state: $\varphi^{\mathrm{M}}=\frac{\mathrm{b}_{\mathrm{y}}}{\beta} \frac{1-e^{-g H}}{g}$ and $\varphi^{K S}=\frac{b_{y}}{\beta} \frac{e^{(r-g) H}-1}{r-g}$

Equations (7.6)-(7.7) are again pure accounting equations. They hold for any saving model. If we now apply them to the saving models analyzed in section 5 , then we just need to replace $b_{y}$ by the relevant steady-state value. So for instance in the class saving model or in the dynastic model, we have $b_{y}=\beta / H$. Therefore:

$$
\varphi^{\mathrm{M}}=\frac{1-\mathrm{e}^{-g H}}{\mathrm{gH}} \text { and } \varphi^{\mathrm{KS}}=\frac{\mathrm{e}^{(r-g) H}-1}{(\mathrm{r}-\mathrm{g}) \mathrm{H}}
$$

[^55]It immediately follows that $\bullet \mathrm{g}>0, \varphi^{\mathrm{M}}<1$, and $\bullet \mathrm{r}-\mathrm{g}>0, \varphi^{\mathrm{KS}}>1$.

Example: With $\mathrm{H}=30$, then $\varphi^{\mathrm{M}}=75 \%$ if $\mathrm{g}=2 \%$ and $\varphi^{\mathrm{M}}=52 \%$ if $\mathrm{g}=5 \%$.
If $\mathrm{r}-\mathrm{g}=3 \%$, then $\varphi^{\mathrm{KS}}=162 \%$. If $\mathrm{r}-\mathrm{g}=5 \%$, then $\varphi^{\mathrm{KS}}=232 \%$. ${ }^{14}$

More generally, if steady-state $b_{y}$ is close to $\beta / H$, or not too much below, which as we saw in section 5 is generally the case with low growth and/or high returns, the same properties hold. That is, $\varphi^{M}$ is structurally below $100 \%$, while $\varphi^{K S}$ is structurally above $100 \%$.

The Modigliani definition $\varphi^{M}$ is particularly problematic, since it fails to recognize that inherited wealth produces flow returns. This mechanically leads to artificially low values for the inheritance share $\varphi^{\mathrm{M}}$ in aggregate wealth accumulation. It is particularly puzzling to see that $\varphi^{M}$ can be equal to $75 \%$ or $52 \%$ in the class saving model - a model where by construction $100 \%$ of wealth comes from inheritance, and where successors are just consuming part of the return to their inheritance and saving the rest. As was pointed out by Blinder (1988), a Rockefeller with zero lifetime labor income would appear to be a lifecycle saver in Modigliani's definition, as long he does not consume the full return to his inherited wealth. In effect, Modigliani defines saving as labor income plus capital income minus consumption (and then defines lifecycle wealth as the capitalized value of past savings, and inherited wealth as aggregate wealth minus lifecycle wealth), while KotlikoffSummers define saving as labor income minus consumption. Given that the capital share is generally larger than the saving rate, this of course makes a big difference.

The Kotlikoff-Summers definition is conceptually more consistent. But in a way it suffers from the opposite drawback. For reasonable parameter values, $\varphi^{M}$ is bound to be larger than $100 \%$ (or close to $100 \%$ ). It is also extremely sensitive to the exact value of r-g.

By applying both definitions $\varphi_{t}{ }^{M}$ and $\varphi_{t}{ }^{\text {Ks }}$ (out-of-steady-state equations (7.4)-(7.5)) to our simulated model based upon two-century-long observed French data, we find the following results (see Figures 24a-b and 25a-b). The uncapitalized inheritance share was about $80 \%$ of aggregate wealth during the $19^{\text {th }}$ century and until World War 1 . It then dropped to $50 \%-60 \%$ in the $1930 \mathrm{~s}-1950 \mathrm{~s}$, and to $40 \%$ in the $1960 \mathrm{~s}-1980 \mathrm{~s}$. It is interesting to note that the historical nadir happens rather late for $\varphi_{t}{ }^{M}$ (in the 1970s), much later than the historical

[^56]nadir for $b_{y t}$ (which occurred in the 1950s). This time lag simply stems from the fact that $\varphi_{t}{ }^{M}$ is based upon the cumulated value of byt of the previous decades. In the benchmark scenario, we find that $\varphi_{t}{ }^{M}$ will be above $60 \%$ in the 2010s and should stabilize above $70 \%$ after 2040 (see Figure 24a). In the low-growth, high-return scenario, we find that $\varphi_{t}{ }^{M}$ stabilizes above $80 \%$ during the $21^{\text {st }}$ century - as in the $19^{\text {th }}$ century (see Figure 24 b).

When we capitalize past bequests, we find that $\varphi_{t}{ }^{\text {KS }}$ is always above $100 \%$, including during the low-inheritance postwar period, and that it is vey sensitive to r-g. In the $19^{\text {th }}$ century, $r$ was so large ( $5 \%-6 \%$ ) and $g$ so low ( $1 \%$ ) that we mechanically find extremly high $\varphi_{t}{ }^{\mathrm{KS}}$ (as large as $450 \%$ in the 1870 s - 1880 s ). ${ }^{115}$ The capitalized bequest share $\varphi_{t}{ }^{\mathrm{KS}}$ was about $250 \%-300 \%$ around 1900-1910, then gradually dropped to about $150 \%$ in the 1960s-1980s. Again the nadir happens very late, due to the same time lags as above, and to the decennial variations in growth and asset returns (e.g. returns were low in the 1970s). In the benchmark scenario, we find that $\varphi_{t}{ }^{\mathrm{KS}}$ stabilizes around $150 \%$ in the $21^{\text {st }}$ century, due to the relatively low projected r-g (see Figure 25a). In the low-growth, highreturn scenario, we find that $\varphi_{t}{ }^{M}$ stabilizes above $250 \%-300 \%$ (the same level as in 19001910), due to the much larger r-g (see Figure 25b).

We conclude from these computations that $\varphi_{t}{ }^{M}$ and $\varphi_{t}{ }^{K S}$ are fragile concepts. First, it is apparent from our French findings that the study of wealth accumulation and inheritance requires long term perspectives and adequate data sources. One should be careful when computing $\varphi_{t}{ }^{M}$ and $\varphi_{t}{ }^{\text {KS }}$ from one data point and steady-state assumptions. In the KSM controversy, both sides used single-data-point estimates of the U.S. inheritance flow $b_{y t}$, and applied steady-state formulas similar to equations (7.6)-(7.7) in order to compute $\varphi_{t}{ }^{M}$ and $\varphi_{t}{ }^{\text {KS }}$. Due to the limitations of U.S. estate tax data (which only covers the very top), they did not have direct measures of the fiscal inheritance flow. So they computed byt by using national wealth estimates and age-wealth profiles for year 1962 (using the 1962 Survey of consumer finances). Kotlikoff and Summers (1981) applied the capitalized definition, and found that $\varphi_{t}{ }^{\text {KS }}$ was about $80 \%$ (and possibly larger than $100 \%$ ) in the U.S. in the 1960s-1970s. By using essentially the same data, Modigliani (1986) concluded that

[^57]$\varphi_{t}{ }^{M}$ was as low as $20 \%-30 \%$ in the U.S. in the 1960 s-1970s. ${ }^{116}$ Using SCF data from the 1980s, Gale and Scholz (1994) found that $\varphi_{t}{ }^{M}$ was closer to $40 \% .^{117}$

These U.S. estimates (say, $\varphi_{t}{ }^{M} \approx 20 \%-40 \%, \varphi_{t}{ }^{K S} \approx 80 \%-100 \%$ ) are somewhat lower than our French estimates for the 1960s-1980s. It could well be that inheritance flows are indeed somewhat lower in the U.S., due to higher economic and (especially) demographic growth, and/or to the crowding out effect of funded pension wealth. However, U.S. estimates are based upon relatively fragile data, so it could also be that they understate true economic inheritance flows. In particular, they tend to rely on relatively low gift-bequest ratios $\mathrm{v}_{\mathrm{t}}$ (and sometime ignore gifts altogether) - a parameter which is hard to estimate in the absence of good fiscal data. This probably contributes to explain why the U.S. literature tends to adopt relatively low inheritance flow-aggregate wealth ratios $b_{w t}$, typically as low as $1 \%-$ $1.5 \%$, while we always find ratios above $2 \%$ in France. ${ }^{118}$

In any case, inheritance flows have probably changed a lot in the U.S. since the 1970s1980s. In order to settle the issue, it would be necessary to construct homogenous, yearly (or decennial) U.S. series on $\beta_{t}, \mu_{t}, b_{w t}$ and $b_{y t}$ up until the present day, as we have done for France. Given U.S. data limitations, one way to proceed would be to use the retrospective information on bequests and gifts available in SCF questionnaires. One needs however to find ways to adequately upgrade these self-reported bequest and gift flows, which in French wealth surveys appear to be far below fiscal flows. ${ }^{119}$

Next, and most importantly, even in a steady-state world with perfect data, none of the definitions $\varphi_{t}{ }^{M}$ and $\varphi_{t}{ }^{K S}$ would be really satisfactory. On the one hand, the Modigliani definition ignores the fact that inheritance produces flow returns, which amounts to

[^58]assuming away the existence of rentiers (this should be part of the empirical demonstration, not of the assumptions). On the other hand, the Kotlikoff-Summers definition $\varphi_{\mathrm{t}}{ }^{\text {KS }}$ is mostly a measure of the magnitude of the capitalized resources available for consumption by successors. It does not really say anything about the relative importance of inherited vs self-made wealth. For instance, in case successors entirely consume their bequest the day they receive it, then $\varphi_{t}{ }^{\text {KS }}$ would still be far above $100 \%$, even though $0 \%$ of aggregate wealth belongs to successors, and $100 \%$ belongs to selfmade individuals who received zero bequest.

The problem with both definitions is that they are based upon a representative-agent approach. In practice, the wealth accumulation process always involves two different kinds of people and wealth trajectories. In every economy, there are inheritors or "rentiers" (people who typically consume part the return to their inherited wealth, and during the course of their lifetime consume more than their labor income), and there are savers or "self-made men" (people who do not inherit much but do accumulate wealth through labor income savings, so that their capitalized consumption is less than their capitalized labor income). A natural way to proceed would be to distinguish explicitly between these two groups, and to define $\varphi_{\mathrm{t}}$ as the wealth share of the second group. The downside is that this definition is more data demanding. While $\varphi_{t}{ }^{\mathrm{M}}$ and $\varphi_{t}{ }^{\mathrm{KS}}$ can be computed using aggregate data, $\varphi_{t}$ requires micro level data on the joint distribution $H_{t}\left(W_{t i}, \tilde{b}_{t i}\right)$ of current wealth and capitalized inherited wealth.

## 8. Concluding comments

What have we learned from this paper? In our view, the main contribution of this paper is to demonstrate empirically and theoretically that there is nothing inherent in the structure of modern economic growth that should lead a long run decline of inherited (non-human) wealth relatively to labor income.

The fact that the "rise of human capital" is to a large extent an illusion should not come as a surprise to macroeconomists. With stable capital shares and wealth-income ratios, the simple arithmetic of growth and wealth accumulation is likely to operate pretty much in the same way in the future as it did in the past. In particular, the r>g logic implies that past wealth and inheritance are bound to play a key role in the future.

As we have shown, there is no reason to expect demographic changes per se to lead to a decline in the relative importance of inheritance. Rising life expectancy implies that heirs inherit later in life. But this is compensated by the rise of inter vivos gifts, and by the fact that wealth also tends to get older in aging societies - so that heirs inherit bigger amounts.

Now, does this mean that the rise of human capital did not happen at all? No. It did happen, in the sense that human capital is what made long run productivity growth and self sustained economic growth possible. We know from the works of Solow and the modern endogenous growth literature that (non-human) capital accumulation alone cannot deliver self-sustained growth, and that human capital is what made $g>0$. The point, however, is that a world with $g$ positive but small (say, $g=1 \%-2 \%$ ) is not very different from a world with $\mathrm{g}=0 \%$.

If the world rates of productivity and demographic growth are small in the very long run (say, by 2050-2100), then the r>g logic implies that inheritance will eventually matter a lot pretty much everywhere - as it did in ancient societies. Past wealth will tend to dominate new wealth, and successors will tend to dominate labor income earners. This is less apocalyptic than Karl Marx: with $\mathrm{g}=0 \%$, the wealth-income ratio rises indefinitely, leading either to a rising capital share, or to a fall in the rate of return, and in any case to non sustainable economic and political outcomes. With $g>0$, at least we have a steady-state. But this is a rather gloom steady-state.

The main limitation of this paper is that we did not attempt to analyze socially optimal tax policy. We have seen in our simulations that $20^{\text {th }}$ century capital taxes, by reducing the differential between $\left(1-\mathrm{T}_{\mathrm{K}}\right) \mathrm{r}$ and g , can and did have a significant impact on the steadystate magnitude of inheritance flows, i.e. on the extent to which wealth perpetuates itself over time and across generations. In order to properly address these issues, one would need however to explicitly introduce inequality and normative concerns into the model, which we did not do in this paper, and which we plan to do in future research. We hope that our results will be useful for scholars interested in capital and inheritance taxation.

The other important - and closely related - limitation of this paper is that we constantly assumed a common rate of return $r$ on private wealth for all individuals. In the real world, the average $r$ is larger than $g$, but the effective $r$ varies enormously across individuals, over time and over assets. Available data and anecdotal evidence suggest that higher wealth individuals tend to get higher average returns (e.g. because of fixed costs in portfolio management, or risk aversion effects, or both). ${ }^{120}$ By assuming a common rate of return, we almost certainly underestimate the inheritance share and overestimate the labor share in capitalized lifetime resources - possibly by large amounts.

In some cases, inherited wealth might also require human skills and effort in order to deliver high returns. That is, it sometime takes labor input to get high capital income. If anything, the empirical relevance of the theoretical distinction between labor and capital income has probably increased over the development process, following the rise of financial intermediation and the separation of ownership and control. I.e. with perfect capital markets, any dull successor should be able to get a high return. But the hererogeneity and potential endogeneity of asset returns are important issues which should be taken into account in a unified positive and normative analysis of inheritance. This raises major conceptual and empirical challenges for future research.

List of files ..... p. 147

## Appendix A: National Accounts Data

The first key data source used in this research is national income and wealth accounts. The main conceptual and methodological issues regarding national accounts and the way we use them, in particular in order to compute the economic inheritance flow, are discussed in the working paper (see sections 3.1 and 3.2). In this appendix we provide the complete series used in this research, as well as additional details about sources, methodology and concepts.

In section A1 we describe our general series on national income $Y_{t}$ and private wealth $W_{t}$ in France. In section A2 we describe how we used these series in order to compute the economic inheritance flow series $B_{t}$. In section A3 we provide supplementary series on the structure of national income $Y_{t}$ (including decomposition by production sector, factor income, taxes and savings, etc.). In section A4 we provide supplementary series on the structure of private wealth $W_{t}$ (including decomposition by types of assets, etc.). Because of the incompleteness of available private wealth series, especially regarding the 19141969 period, we have to construct our own annual series, which we do by estimating an accumulation equation for private wealth in France, using savings flows from national accounts; full details on this method and resulting series are provided in section A5. Finally, in section A6 we provide supplementary series on price indexes in France, which we use at various points in the previous tables.

## A.1. General national accounts series for France: $\underline{Y}_{t}$ and $\mathbf{W}_{\mathbf{t}}$ (Tables A1-A2)

Our national income series $Y_{t}$ and private wealth series $W_{t}$ are reported on Table A1 (annual series) and Table A2 (decennial averages). Here we describe how these tables were constructed.

## Col. (1) of Tables A1-A2: National income Yt in current prices

Our basic series for national income $Y_{t}$ are reported on col. (1), expressed in current billions currency, by which we mean current billions euros for the 1949-2009 period and current billions old francs for the 1820-1948 period. ${ }^{1}$

[^61]National income $Y_{t}$ is defined according to the standard international definition: it is equal to gross domestic product minus capital depreciation plus net foreign factor income. ${ }^{2}$

We use the official Insee series for the 1949-2009 period, ${ }^{3}$ and the Villa (1994) retrospective series for the 1896-1949 period, with minor adjustments so as to ensure continuity in 1948-1949. ${ }^{4}$ The various subcomponents of $Y_{t}$ are given in section A3 below.

There also exists annual series for French national income covering the 1820-1896 period. But we do not feel that the year-to-year variations depicted in these series are fully reliable. In addition we do not really need annual series for our purposes. Therefore prior to 1896 we only provide decennial averages estimates of national income. I.e. the value of 11.3 billions old francs reported for 1820 on col.(1) of Table A2 corresponds to an estimated arithmetic average of national income $Y_{t}$ over the years 1820-1829, the value of 13.5 billions old francs reported for 1830 corresponds to an estimated arithmetic average over the years 1830-1839, and so on. ${ }^{5}$ We computed the average 1820-1929 to 18901899 estimates by using the annual series provided by Bourguignon and Lévy-Leboyer (1985), anchored to the 1900-1909 and 1910-1913 values obtained from our annual series. ${ }^{6}$ If we were to use alternative series due to other authors such as Toutain (1997),

[^62]we would obtain similar decennial averages and overall profiles of national income growth over the course of the $19^{\text {th }}$ century. ${ }^{7}$

Col. (2) of Tables A1-A2: Aggregate private wealth $W_{t}$ in current prices

Our basic aggregate series for private wealth $W_{t}$ are reported on col. (2), again expressed in current billions currency, as defined above.

Private wealth $W_{t}$ is defined as the market value of all tangible assets (in particular real estate assets) and financial assets owned by private individuals (i.e. households), minus their financial liabilities. Private wealth $W_{t}$ is estimated at asset market prices prevailing on January $1^{\text {st }}$ of each year.

We use the official Insee-Banque de France series for the 1970-2009 period. I.e. for years 1970-2009, the value of private wealth $W_{t}$ reported on Table A1 is simply equal to the net worth of the personal (household) sector balance sheet published by Insee for the corresponding year. ${ }^{8}$ Complete breakdowns of these $W_{t}$ 1970-2009 series by asset categories, as well as net worth series for the government and corporate sectors, are provided in section A4 below (see Tables A13-A16).

[^63]Prior to 1970, there exists no official estimate of aggregate private wealth in France, so we had to use various non-official estimates and to compute our own series. As we explain in the working paper (see section 3.2), non-official private wealth estimates are plentiful and relatively reliable for the 1820-1913 period, so we simply used the best decennial averages available in the historical literature. ${ }^{9}$ The period 1914-1969 is the most problematic: we only have (relatively) reliable private wealth estimates for 1925 and 1954, and we computed our own annual private wealth $W_{t}$ series by estimating an accumulation equation for private wealth (see section A5 below).

## Col. (3)-(4) of Tables A1-A2: Aggregate $Y_{t}$ and $W_{t}$ in 2009 consumer prices

Col. (3) and (4) of Tables A1 and A2 were obtained by multiplying col.(1) and (2) by $P_{2009} / P_{t}$, where $P_{t}$ is the consumer price index (CPI) reported on col.(1) of Table A20. This is done for illustrative purposes only. Over such long time periods, we are not sure that constant price series are really meaningful.

## Col. (5)-(12) of Tables A1-A2: Per capita \& per adult $\mathrm{Y}_{\underline{t}}$ and $\mathrm{W}_{t}$

Col.(5) to (12) of Tables A1 and A2 were obtained by dividing col. (1) to (4) by total population or adult population (col. (1) and (7) of Table C1). We find that per adult national income $y_{t}$ rose from 602 francs in the 1820s to 1,637 francs in 1910-1913 and 36,197 euros in 2008, while per adult private wealth $w_{t}$ rose from 3,302 francs in the 1820s to 10,713 francs in 1910-1913 and 203,696 euros in 2008 (see Table A2, col. (7) and (8)). Expressed in 2009 consumer prices (whatever it means), per adult national income $y_{t}$ rose from 2,991 euros in the 1820s to 5291 euros in 1910-1913 and 36,342 euros in 2008, while per adult private wealth $w_{t}$ rose from 16,413 euros in the 1820 s to 34,626 euros in 1910-1913 and 204,511 euros in 2008 (see Table A2, col. (11) and (12)).

Col. (13) of Tables A1-A2: Wealth-income ratio $\beta_{t}=W_{t} / \underline{Y}_{t}$

Col. (13) of Tables A1 and A2 was obtained by dividing col. (2) by col. (1). By construction, it is also equal to col. (4) divided by col. (3), or col. (6) by col. (5), etc. We find that the ratio

[^64]$\beta_{t}$ between aggregate private wealth $W_{t}$ and national income $Y_{t}$ was equal to $549 \%$ in the 1820s, 654\% in 1910-1913, and 563\% in 2008.

## Col. (14)-(16) of Tables A1-A2: Disposable income ratios

We choose to use national income rather than (personal) disposable income as the income denominator when we compute wealth-income ratios. However it is useful to have in mind what the results of the computations would be if one were to use disposable income as denominator. On col. (14) of Tables A1-A2 we report the ratio between disposable income and national income; this ratio was equal to $95 \%$ in the 1820s and in 1910-1913 and to $70 \%$ in $2008 .{ }^{10}$ Col. (15) of Tables A1-A2 was obtained by multiplying col.(11) by col. (14); we find that per adult disposable income $\mathrm{y}_{\mathrm{dt}}$ (expressed in 2009 consumer prices) rose from 2,842 euros in the 1820s to 5,005 euros in 1910-1913 and 25,281 euros in 2008. Col. (16) of Tables A1-A2 was obtained by dividing col. (13) by col. (14); we find that the ratio between aggregate private wealth and disposable income was 578\% in the 1820s, 692\% in 1910-1913 and 809\% in 2008.

## A.2. Computation of the economic inheritance flow series $B_{t}$ (Tables A3-A4)

Our economic inheritance flow series $B_{t}$ and related ratios are reported on Table A3 (annual series) and Table A4 (decennial averages). Here we describe how these tables were constructed.

Col. (1) to (6) of Tables A3-A4: $b_{y t}=\mu_{\underline{t}}^{*} \mathrm{~m}_{\underline{t}} \underline{\beta}_{t}$ and $b_{\underline{w t}}=\mu_{\underline{t}}^{*} \mathrm{~m}_{\underline{t}}$

As we explain in the working paper (see section 3.1), the basic accounting equation relating the aggregate economic inheritance flow $B_{t}$ and aggregate private wealth $W_{t}$ is the following:

$$
\begin{equation*}
\mathrm{B}_{\mathrm{t}}=\mu_{\mathrm{t}}^{*} \mathrm{~m}_{\mathrm{t}} \mathrm{~W}_{\mathrm{t}} \tag{A.1}
\end{equation*}
$$

Where $\mu_{t}{ }^{*}$ is the gift-corrected ratio between average wealth of (adult) decedents and average wealth of the (adult) living, and is estimated from available data on the age profile

[^65]of wealth (see Appendix B2); and $m_{t}$ is the (adult) mortality rate and comes from standard demographic data (see Appendix C1).

Alternatively, equation (A.1) can also be expressed in terms of inheritance-income and inheritance-wealth aggregate ratios:

$$
\begin{gather*}
\mathrm{b}_{\mathrm{yt}}=\mathrm{B}_{\mathrm{t}} / Y_{\mathrm{t}}=\mu_{\mathrm{t}}^{*} \mathrm{~m}_{\mathrm{t}} \mathrm{~W}_{\mathrm{t}} / Y_{\mathrm{t}}=\mu_{\mathrm{t}}^{*} \mathrm{~m}_{\mathrm{t}} \beta_{\mathrm{t}}  \tag{A.2}\\
\mathrm{~b}_{\mathrm{wt}}=\mathrm{B}_{\mathrm{t}} / \mathrm{W}_{\mathrm{t}}=\mu_{\mathrm{t}}^{*} \mathrm{~m}_{\mathrm{t}} \tag{A.3}
\end{gather*}
$$

The computations reported on Tables A3-A4 follow directly from the mechanical application of these formulas. On col. (1) of Tables A3-A4 we report the aggregate wealthincome ratio $\beta_{t}$, which we borrow from col. (13) of Tables A1-A2. On col. (2) of Tables A3A4 we report the adult mortality rate $\mathrm{m}_{\mathrm{t}}$, which we borrow from col. (11) of Table C1. On col. (3) of Tables A3-A4 we report the gift-corrected $\mu_{\mathrm{t}}{ }^{*}$ ratio, which we borrow from col. (12) of Table B5. Col. (4) of Tables A3-A4 was then obtained by multiplying col. (1), (2) and (3) (i.e. $b_{y t}=\mu_{t}{ }^{*} m_{t} \beta_{t}$ ). We find that the aggregate economic inheritance flow-national income ratio $b_{y t}$ was equal to $20.3 \%$ in the 1820 s, $22.7 \%$ in $1910-1913$, and $14.5 \%$ in 2008. Col. (5) of Tables A3-A4 was obtained by multiplying col. (2) and (3) (i.e. $b_{w t}=\mu_{t}^{*}$ $m_{t}$ ). We find that the aggregate economic inheritance flow-private wealth ratio $b_{w t}$ was equal to $3.7 \%$ in the $1820 \mathrm{~s}, 3.5 \%$ in 1910-1913, and $2.6 \%$ in 2008. We also report on col. (6) of Tables A3-A4 the estate multiplier ratio $e_{t}=W_{t} / B_{t}=1 / b_{w t}$ : col.(6) is simply equal to one divided by col. (5). We find that according to our economic inheritance flow computations, aggregate private wealth was equal to 27.0 years of inheritance flow in the 1820s, 28.9 years in 1910-1913 and 38.7 years in 2008.

## Col. (7) to (9) of Tables A3-A4: $B_{t}=\mu_{t}^{*} m_{t}$

We also report the results of our economic inheritance flow computations expressed in billions currency and not only in ratios. On col. (7) of Tables A3-A4 we report our aggregate private wealth series $W_{t}$, which we borrow from col. (2) of Tables A1-A2. Col. (8) of Tables A3-A4 was then obtained by multiplying col. (2), (3) and (7) (i.e. $B_{t}=\mu_{t}^{*} m_{t}$ $W_{t}$ ). We find that the aggregate economic inheritance flow was equal to 2.3 billions francs in the 1920s, 9.6 billions francs in 1910-1913, and 246.7 billions euros in 2008. For the
purpose of comparison, we also report the ratio $B_{t} / B_{t}{ }^{f}$ between our economic inheritance flow and our fiscal inheritance flow series: col. (9) of Tables A3-A4 was obtained by dividing col. (8) of Tables A3-A4 by col. (10) of Tables B1-B2; we find a ratio of $105 \%$ in the 1820s, 111\% in 1910-1913, and 115\% in 2008.

## Col. (10) to (12) of Tables A3-A4: $b_{t}=\mu_{t}^{*} \underline{\beta}_{\underline{t}} \underline{y}_{\underline{t}}$

We also report our economic inheritance flow estimates expressed in per capita terms. If we note $b_{t}$ average per decedent inheritance, and $y_{t}$ average per adult national income, then the equations above can also be written as follows:

$$
\begin{equation*}
b_{t}=\mu_{t}^{*} \beta_{t} y_{t} \tag{A.4}
\end{equation*}
$$

On col. (10) of Tables A3-A4 we report per adult income $y_{t}$, which we borrow from col. (7) of Tables A1-A2. Col. (11) of Tables A3-A4 was obtained by multiplying col. (1), (3) and (10) (i.e. $b_{t}=\mu_{t}^{*} \beta_{t} y_{t}$ ). On col. (12) of Tables A3-A4 we report the ratio $b_{t} / y_{t}$. We find that according to our economic inheritance flow computations average inheritance was equal to 5,497 francs in 1820s (i.e. 9.1 years of average income), 17,406 francs in 1910-1913 (i.e. 10.6 years of average income), and 453,344 euros in 2008 (i.e. 12.5 years of average income).

## Col. (13) to (16) of Tables A3-A4: fiscal flow ratios

For comparison purposes we also report on Tables A3-A4 our fiscal inheritance flow estimates. On col. (13) of Tables A3-A4, we report ratios $B_{t}{ }^{f} / Y_{t}$ between fiscal inheritance flow and national income, which we borrow from col. (12) of Tables B1-B2. On col. (14) of Tables A3-A4, we report ratios $B_{t}{ }^{f} / W_{t}$ between fiscal inheritance flow and private wealth, which we borrow from col. (13) of Tables B1-B2. We also report the fiscal estate multiplier $e_{t}^{f}=W_{t} / B_{t}^{f}$ on col. (15) of Tables A3-A4 (equal to one divided by col. (14)) and the fiscal $b_{t}{ }^{f} / y_{t}$ ratio on col. (16) of Tables A3-A4 (equal to col. (13) divided by the mortality rate, i.e. by col. (2)). We find that according to fiscal data average inheritance was equal to 8.5 years of average income in the 1820s, 9.5 years in 1910-1913 and 10.9 in 2008.

## A.3. Supplementary series on the structure of national income $Y_{t}$ (Tables A5-12)

Detailed annual series on the structure of national income $Y_{t}$ in France over the 1896-2008 period (including decomposition by institutional production sector, factor income, taxes and savings, etc.) are reported on Tables A5 to A11. Prior to 1896, available series are more rudimentary. The only series that we can provide for the entire 1820-2008 period are decennial-averages estimates of capital and labor shares, rates of return, aggregate tax rates and savings rates; these summary macro variables are reported on Table A12. These series are useful in order to better understand how the general structure of income and wealth has evolved in France over the past two centuries. They also play important specific roles at various points in this research. In particular, we need saving rates series for estimating the private wealth accumulation equation (see Appendix A5 below), and we need both saving rates series and rates of return series for simulating the dynamics of the age-wealth profile (see Appendix D). The computation of average macroeconomic rates of return to private wealth requires detailed series on factor income and taxes. Rates of return play a critical role in this research. So we try to explain carefully how Tables A5 to A12 were constructed.

Table A5: National income vs gross domestic product (1896-2008)

On Table A5 we report the most basic decomposition of national income $Y_{t}$ :

$$
\begin{gather*}
Y_{t}=Y_{p t}+F Y_{t}  \tag{A.5}\\
Y_{p t}=G D P_{t}-K D_{t} \tag{A.6}
\end{gather*}
$$

With: $Y_{t}=$ national income (i.e. net national product)
$Y_{p t}=$ net domestic product
$F Y_{t}=$ net foreign factor income
$\mathrm{GDP}_{\mathrm{t}}=$ gross domestic product
$K D_{\mathrm{t}}=$ capital depreciation

On col. (1)-(3) and (10)-(11) of Table A5, we report values of $Y_{t}, Y_{p t}, F Y_{t}, G D P_{t}$ and $K D_{t}$ expressed in billions current currency. On col. (4)-(9) and (12)-(13) of Table A5, as well as on all columns of Tables A6-A10, we report values expressed as fractions of national income $Y_{t}$ (or other aggregates). All series reported on Tables A5-A10 come directly from

Insee official series for the 1949-2008 period, and from the Villa (1994) series for 18961948 period, with minor adjustments which we describe as they come. ${ }^{11}$

Col. (4)-(8) of Table A5 show that changes in net foreign factor income $F Y_{t}$ are almost entirely due to changes in net foreign capital income $\mathrm{FY}_{\mathrm{Kt}}$ (net foreign labor income $\mathrm{FY}_{\mathrm{Lt}}$ seems to have always been relatively small). ${ }^{12}$ Most importantly, they show that net foreign capital income made up approximately $4 \%$ of national income at the eve of World War 1 , then fell abruptly during war years (due to foreign assets repudiation and inflation), and never recovered: from the 1920s up until 2008, it has generally been about 0\%-1\% of national income (this is consistent with the fact that the net foreign asset position of France seems to have been relatively small throughout this period; see section A4 below). However gross flows have risen enormously in recent decades (due to financial globalization): in 1978, gross capital income inflow and outflow were around $1 \%$ of national income; in 2008, both were around 10\% of national income.

On col. (9) we report the value of net foreign tax and transfers, which we note $\mathrm{FT}_{\mathrm{t}}{ }^{13}$ According to standard international definitions, this should added to national income $Y_{t}$ in order to compute so-called "national disposable income". Note that $\mathrm{FT}_{\mathrm{t}}$ has actually been negative since the 1950s up to 2008 (around $-1 \%$ of national income), due mostly to the remittances of immigrant workers. ${ }^{14}$

[^66]Col. (12)-(13) of Table A5 show that capital depreciation seems to have been relatively stable around 9\%-11\% of gross domestic product between 1900 and the 1970s, and then gradually rose during the past three decades, up to about $13 \%-14 \%$ today. Of course capital depreciation estimates are notoriously fragile, and some of the short-run variations reported on Table A5 might partly be due to measurement limitations (rather than to real changes in the age structure and depreciation rates of capital inputs). Given that we are mostly interested in long run evolutions, we feel that these data limitations are not really relevant for our purposes. ${ }^{15}$

Table A6: decomposition by institutional production sectors (1896-2008)

Net domestic product $Y_{p t}$ can be further decomposed into the net product (net-of-capitaldepreciation, net-of-production-taxes value-added) of the various institutional production sectors used in national accounts:

$$
\begin{equation*}
Y_{p t}=Y_{h t}+Y_{s e t}+Y_{c t}+Y_{g t}+T_{p t} \tag{A.7}
\end{equation*}
$$

With:
$Y_{h t}=$ net product of the housing sector ${ }^{16}$
$Y_{\text {set }}=$ net product of the self-employment sector ${ }^{17}$
$Y_{c t}=$ net product of the corporate sector (non-financial + financial) ${ }^{18}$

[^67]$\mathrm{Y}_{\mathrm{gt}}=$ net product of the government sector (incl. the non-profit sector) ${ }^{19}$
$\mathrm{T}_{\mathrm{pt}}=$ production taxes (incl. value-added taxes) ${ }^{20}$

As one can see from Table A6, the sectoral structure of national income has changed in important ways in France during the 1896-2008 period. First, the implicit average production tax rate, which we define as production taxes divided by factor-price national income (i.e. $T_{p t}$ divided by $Y_{t}-T_{p t}$ ), was about $7 \%-8 \%$ prior to World War 1, then rose during the interwar and postwar period, and stabilized around $17 \%-18 \%$ since the 1950 s up to 2008. ${ }^{21}$

Next, the share of the housing sector in (factor-price) national income has gone through a U-shaped pattern over the past 100 years: it was about $8 \%$ prior to World War 1, then fell abruptly to $3 \%$ in 1920 , recovered during the interwar, fell again during World War 2, with a nadir at only $2 \%$ in 1945, and then gradually recovered during the past 60 years, up to $8 \%-$ $9 \%$ in the 1990 s-2000s. ${ }^{22}$ These large historical variations seem to reflect (at least in part) the evolution of rent control policies. ${ }^{23}$

Next, the share of the government sector (whose contribution to net product in existing national accounts is simply measured by the wage bill of the government sector) ${ }^{24}$ rose dramatically. It was only $2 \%-3 \%$ of (factor price) national income prior to World War 1, then rose to $5 \%-6 \%$ during the interwar, $12 \%-13 \%$ in the postwar period, before (apparently) stabilizing around $19 \%-20 \%$ in the 1990s-2000s.

[^68]Next, the share of the self-employment sector declined even more dramatically. It was about $50 \%$ at the eve of World War 1, about $40 \%$ in the aftermath of World War 2, and gradually declined to little more than $10 \%$ in the 2000 s. At the same time, the share of the corporate sector gradually rose from about $30 \%$ of (factor price) national income around 1900 to about $60 \%$ during the 1990s-2000s.

Finally, note that the long run evolution of the relative shares of the government, selfemployment and corporate sectors (which are the three production sectors using labor input) is broadly consistent with the corresponding evolution of the employment structure of France. ${ }^{25}$

Table A7: profits \& wages in the corporate sector (1896-2008)

On Table A7 we report the standard decomposition of corporate value-added into wages and profits. That is, we break down net corporate product $\mathrm{Y}_{\text {ct }}$ into a labor income component $Y_{\text {Lct }}$ and a capital income component $Y_{\text {Kct }}$ :

$$
\begin{equation*}
Y_{c t}=Y_{L c t}+Y_{K c t} \tag{A.8}
\end{equation*}
$$

With: $Y_{\text {Lct }}=$ total wage bill of the corporate sector (incl. social contributions)
$Y_{\text {Kct }}=Y_{\text {ct }}-Y_{\text {Lct }}=$ net corporate profits

One can then define the corporate capital share $\alpha_{\mathrm{ct}}=Y_{\mathrm{kct}} / Y_{\mathrm{ct}}$ and the labor share 1- $\alpha_{\mathrm{ct}}=$ $Y_{\text {Lct }} / Y_{\text {ct }}$ in net corporate product. We choose to focus upon net-of-depreciation functional shares, first because they are more meaningful from an economic viewpoint, and next because this is what we need in order to compute average rates of return on private wealth (see below). For the purpose of comparison with other studies, we also report on Table 6 series for the gross profit share in gross corporate product $\left(\mathrm{Y}_{\mathrm{Kct}}+\mathrm{KD}_{\mathrm{ct}}\right) /\left(\mathrm{Y}_{\mathrm{ct}}+\mathrm{KD}_{\mathrm{ct}}\right)$

[^69](where $\mathrm{KD}_{\mathrm{ct}}$ denotes capital depreciation of the corporate sector) and the corresponding labor share in gross corporate product $\mathrm{Y}_{\mathrm{Lct}}\left(\mathrm{Y}_{\mathrm{ct}}+\mathrm{KD}_{\mathrm{ct}}\right){ }^{26}$ Gross functional shares are often used in policy discussions and typically deliver labor shares around two thirds and capital shares around one third.

Note that pre-1949 factor income data is definitely of lower quality than that used in post1949 Insee series, and one should be cautious when interpreting pre-1949 variations and levels of labor and capital shares.

During the 1949-2008 period, labor and capital shares in France appear to display the standard two-thirds-one-third pattern. During the 1950s-1960s, the gross profit share is relatively stable around $30 \%-32 \%$ of gross corporate product; during the 1990s-2000s, the gross profit share is relatively stable around $32 \%-34 \%$ of gross domestic product (see Table A7, col. (8)). Two caveats are in order, however. First, there are important medium term variations. One observes large U-shaped fluctuations during the 1970s-1980s: the gross profit share suddenly falls from $32 \%$ in 1973-1974 to $25 \%$ in 1981-1982, ${ }^{27}$ and then returns to $33 \%$ in 1986-1987. ${ }^{28}$ Next, if one looks at net profit shares in net corporate product, then all capital shares are reduced substantially (typically by about 10 points), which makes the medium term variations look even bigger. The net profit share was about $20 \%-22 \%$ of net corporate product in France during the 1950s-1960s, then fell to as little as $12 \%$ in the late 1970 s-early 1980s, and was again about $20 \%-22 \%$ during the 1990s2000s (see Table A7, col.(2)). This is fairly different from the standard two-thirds-one-third textbook pattern.

Time variations in the way profits are used are also significant. Over the 1949-2008 period, corporate income taxes were relatively stable around $5 \%$ of net corporate product (typically between a quarter and a third of net profits), and distributed profits (dividend and interest payments) were relatively stable around $10 \%$ of net corporate product; ${ }^{29}$ retained earnings on the other hand were highly volatile and absorbed most of the time variations in

[^70]the profit share (resulting in large negative retained earnings in the late 1970s-early 1980s). But one can also notice that retained earnings were structurally higher in the reconstruction period than in recent decades: on average they made about 7\% of net corporate product in the 1950s-1960s (3\%-4\% of national income), versus about 3\% in the 1990s-2000s (1\%-2\% of national income). ${ }^{30}$

Available series for the 1896-1949 period broadly confirm the view of a long run stability of capital shares (with gross profit shares around $30 \%-35 \%$ and net profit shares around $20 \%-25 \%$ ). They also show very large short run and medium run variations, and somewhat bigger average capital shares than contemporary levels. ${ }^{31}$ The Villa series indicate that the net profit share was about $15 \%-20 \%$ around 1900, and rose to over $30 \%$ in 1910-1913. ${ }^{32}$ It was again over $30 \%$ during the 1920s (a level unobserved in the post1949 period), fell during the 1930s, and reached negative values in war years (when capital depreciation slightly exceeded gross profits). Prior to World War 1 there was no corporate income tax, retained earnings were small, so that distributed profits were as large as $15 \%-20 \%$ of net corporate product (far above all levels observed in the post-1949 period). The Villa series also indicate very large levels of retained earnings, especially during the 1920s. This seems consistent with the reconstruction story. Pre-1949 retained earnings estimates have been challenged by a number of scholars, however, and it is possible that the Villa's extremely high retained earnings levels for 1910-1913 and the interwar period are somewhat overestimated. ${ }^{33}$

Table A8: capital \& labor shares in national income (1896-2008)

[^71]Capital income does not come solely from the corporate sector. On Table A8 we break down the net product of the various sectors in order to compute capital and labor shares in total national income. We proceeded as follows.

Housing sector: by definition, the net product of the housing sector $Y_{h t}$ solely generates capital income. I.e. $Y_{h t}=Y_{K h t}$ and $\alpha_{h t}=100 \%{ }^{34}$

Self-employment sector: for simplicity, we choose to break down the net product of the self-employment sector $Y_{\text {set }}$ into a capital income component $Y_{\text {Kset }}$ and a labor income component $Y_{\text {Lset }}$ by assuming the same capital share as in the corporate sector. I.e. we assume $\alpha_{\text {set }}=\alpha_{c t}{ }^{35}$

Government sector: by definition, the net product of the government sector $\mathrm{Y}_{\text {ht }}$ solely generates labor income. l.e. $Y_{g t}=Y_{\text {Lgt }}$ and $\alpha_{g t}=0 \% .{ }^{36}$ However, although the government does not generate capital income out of its productive economic activity, ${ }^{37}$ it does generate capital income out of its public-finance, borrowing activity, namely government interest payments on public debt. The government also receives capital income on its financial assets (e.g. if the government owns equity shares in corporations). We define net government interest payments (which we note $\mathrm{Y}_{\mathrm{Kgt}}$ ) as the excess of capital income paid

[^72]by the government sector over capital income received by the government. Whether $\mathrm{Y}_{\mathrm{kgt}}$ should be taken into account in total capital income depends on the specific purpose one has in mind (see below). In order to compute average returns to private wealth (which is our primary purpose), the most consistent solution is to include net government interest payments in the definition of total capital income. In practice, this does not make a very large difference, as the detailed series reported on Table A8 illustrate (net government interest payments have usually been less about $1 \%-2 \%$ of national income). ${ }^{38}$

Foreign sector: we simply use the net foreign capital income $\mathrm{FY}_{\mathrm{Kt}}$ and labor income FY Lt series reported on Table A5 above.

We then define aggregate capital income $\mathrm{Y}_{\mathrm{Kt}}$ (excluding government interest) and labor income $Y_{L t}$ by summing up the various components:

$$
\begin{align*}
& Y_{K t}=Y_{K c t}+Y_{h t}+Y_{K s e t}+F Y_{K t}  \tag{A.9}\\
& Y_{L t}=Y_{L c t}+Y_{L s e t}+Y_{g t}+F Y_{L t} \tag{A.10}
\end{align*}
$$

By construction the sum of these two terms is equal to factor-price national income:

$$
\begin{equation*}
Y_{\mathrm{Kt}}+Y_{\mathrm{Lt}}=Y_{\mathrm{t}}-\mathrm{T}_{\mathrm{pt}} \tag{A.11}
\end{equation*}
$$

We define the aggregate capital share $\alpha_{t}$ (excluding government interest) and labor share $1-\alpha_{t}$ in factor price national income as follows:

$$
\begin{align*}
& \alpha_{\mathrm{t}}=Y_{\mathrm{Kt}} /\left(Y_{\mathrm{t}}-T_{\mathrm{pt}}\right)  \tag{A.12}\\
& 1-\alpha_{\mathrm{t}}=Y_{\mathrm{Lt}} /\left(\mathrm{Y}_{\mathrm{t}}-T_{\mathrm{pt}}\right) \tag{A.13}
\end{align*}
$$

[^73]In order to compute average rates of return to private wealth, one needs to include government interest and to define total capital income $Y_{K t}{ }^{*}=Y_{\mathrm{Kt}}+Y_{\mathrm{Kgt}}$ and total capital share $\alpha_{t}^{*}=Y_{k t}{ }^{*} /\left(Y_{t}-T_{p t}\right)=\alpha_{t}+\alpha_{g t}\left(\right.$ with $\left.\alpha_{g t}=Y_{k g t}\left(Y_{t}-T_{p t}\right)\right)$.

On Table A8, we report primary (pre-tax) functional shares series using both definitions, i.e. including government interest (see col.(13)-(14)) and excluding government interest (see col.(15)-(16)). Note that when we include government interest the capital and labor shares do not exactly sum up to $100 \%$. This is because government interest enters into the definition of total capital income $\mathrm{Ykt}^{*}$ but not in the definition of national income $\mathrm{Y}_{\mathrm{t}}$ (it is treated as a pure transfer by national accounts, not as additional output). Both sets of series are very close and depict the same picture: ${ }^{39}$ with the exception of the mid-century nadir, the capital share has been fairly stable over the $20^{\text {th }}$ century, albeit at somewhat higher levels in the early $20^{\text {th }}$ century ( $30 \%-35 \%$ ) than in the late $20^{\text {th }}$ century ( $25 \%-30 \%$ ). This is due for the most part to the structural rise of the government sector (which does not distribute capital income out of its productive activity). Note also that the (sharp) U-shaped evolution of rental income generates a (moderate) U-shaped pattern for the overall capital share. I.e. the sharp rise of rental income explains why the capital share is now higher than what in the immediate postwar period, in spite of the fact that corporate capital shares are currently about the same level as in the 1950s-1960s.

## Table A9: taxes \& transfers (1896-2008)

On Table A9 we report national accounts series on taxes and transfers. Taxes raise complex general equilibrium tax incidence issues, which national accounts series alone are of course unable to solve. The computations reported in these tables rely on simple tax incidence assumptions (detailed below), which in our view are valid as a first approximation, but which would definitely deserved to be improved.

Following standard national accounts categories we distinguish four types of taxes:

$$
\begin{equation*}
T_{t}=T_{p t}+T_{c t}+T_{i t}+S C_{t} \tag{A.13}
\end{equation*}
$$

With:

[^74]$T_{t}=$ total tax revenues
$\mathrm{T}_{\mathrm{pt}}=$ production taxes revenues ${ }^{40}$
$\mathrm{T}_{\mathrm{ct}}=$ corporate income and wealth taxes revenues ${ }^{41}$
$T_{\text {it }}=$ personal income and wealth taxes revenues ${ }^{42}$
$\mathrm{SC}_{\mathrm{t}}=$ social contributions revenues ${ }^{43}$

Total tax revenues rose from less than $10 \%$ of national income prior to World War 1 to about $15 \%-20 \%$ in the interwar, $30 \%$ by 1950, and $50 \%$ in the 1990s-2000s. In the early 20h century, tax revenues came mostly from production taxes. The interwar rise in tax revenues was largely due to the appearance of personal and corporate income taxes. The postwar rise was due to all type of taxes: production taxes, income taxes, and particularly social contributions (see Table A8, col. (1)-(5)).

We assume that corporate taxes $T_{\text {ct }}$ fall entirely on capital, and that social contributions $S C_{t}$ fall entirely on labor. Regarding personal taxes $T_{i t}$, we proceed as follows. First we take away bequest and gift taxes $\mathrm{T}_{\mathrm{Bt}}$ from $\mathrm{T}_{\mathrm{it}}$, and assume they fall on capital. Next, in order to decompose other personal taxes $\mathrm{T}_{\mathrm{it}}-\mathrm{T}_{\mathrm{Bt}}$ (which in practice are mostly personal income taxes) into a capital tax component $T_{\text {Kit }}$ and a labor tax component $T_{\text {Lit }}$, we assume that other personal taxes fall proportionally on $50 \%$ of capital income $Y_{K t}{ }^{*}$ and on $100 \%$ of labor income $\mathrm{Y}_{\mathrm{Lt} .}{ }^{44}$ The $50 \%$ coefficient on capital income is supposed to take into account the fact that a large fraction of capital income is not subject to the personal income tax (imputed rent, retained earnings, tax exempt savings accounts, etc.) or benefits from lighter tax treatment or reduced rates. ${ }^{45}$

[^75]Neglecting production taxes for the time being, we then define total capital taxes $T_{K t}$ and total labor taxes $\mathrm{T}_{\mathrm{Lt}}$ as follows:

$$
\begin{align*}
& \mathrm{T}_{\mathrm{Kt}}=\mathrm{T}_{\mathrm{ct}}+\mathrm{T}_{\mathrm{Kit}}+\mathrm{T}_{\mathrm{Bt}}  \tag{A.14}\\
& \mathrm{~T}_{\mathrm{Lt}}=\mathrm{SC}_{\mathrm{t}}+\mathrm{T}_{\mathrm{Lit}} \tag{A.15}
\end{align*}
$$

Note that bequest and gift taxes have generally raised about $0.5 \%-1 \%$ of national income, both around 1900-1910 and around 2000; at the mid $20^{\text {th }}$ century inheritance nadir, it was as little as $0.1-.0 .2 \%$. This U-shaped pattern of inheritance tax revenues is for the most part the mechanical consequence of the U-shaped pattern of the inheritance flow itself. The average tax rate on bequests and gifts, defined as $T_{B t} / B_{t}$ (where $B_{t}$ is the economic inheritance flow borrowed from Table A3), has been relatively stable around 5\% throughout the 1896-2008 period (see Table A9, col. (15)). Prior to World War 1, bequest and gift taxes made most of capital taxes. The balance started shifting in the interwar period, and especially in the postwar period. Nowadays taxes on the capital income flows (either at the corporate or personal level) vastly dominate taxes on the transmission of capital (see Table A9, col.(6)-(7)).

By including inheritance taxes into total capital income taxes, we are in effect assuming in our simulations (Appendix D) that they are paid out of the yearly return to capital, so that they reduce after-tax returns to private wealth, just like other capital taxes. Maybe it would be preferable to treat them separately and to assume that inheritance taxes are paid out of inherited wealth, so that they reduce wealth transmission flows in the simulated model. One could then take into account the progressivity of inheritance taxes (most of the population pays inheritance taxes close to $0 \%$, while a minority pays much more than $5 \%$ ). Given our aggregate focus, however, it seems simpler as a first approximation to just include them into capital taxes.

By dividing $T_{K t}$ by $Y_{K t}{ }^{*}$ and $T_{L t}$ by $Y_{L t}$ we obtain the average implicit tax rates on capital $T_{K t 0}$ and on labor $\mathrm{T}_{\text {Lto }}$ (excluding production taxes) reported on col.(9)-(10). Because social contributions are so large (almost half of total taxes, and about two thirds of total labor

[^76]taxes), the labor tax rate vastly exceeds the capital tax rate: in the 1990s-2000s, the labor tax rate was about $45 \%$, while the capital tax rate was less than $25 \%$.

Note however that social contributions SC $_{t}$ finance for the most part replacement income $Y_{R t}$, i.e. transfers received by labor income earners when they do not work, and which are generally proportional to past labor income and social contributions (pensions, unemployment benefits). On col. (16)-(18) of Table A9 we report total government (monetary) transfers $\mathrm{TR}_{\mathrm{t}}$, which we break down into replacement income $\mathrm{Y}_{\mathrm{Rt}}$ and "pure transfers" $\mathrm{TR}_{0 \mathrm{t}} ;{ }^{46}$ in the 2000s, total transfers made about $20 \%$ of national income, out of which about $18 \%$ were replacement income and $2 \%$ were pure transfers. In case one deducts "replacement taxes" from labor taxes, i.e. the fraction of social contributions financing replacement income (this amounts to treating these as forced savings rather than taxes), then the labor tax rate in the 2000s drops from about $45 \%$ to about $25 \%-30 \%$, i.e. somewhat below the capital tax rate (see Table A9, col. (11)). ${ }^{47}$

As a first approximation, we choose to view production taxes $T_{p t}$ as broad taxes falling proportionally on total factor income $\mathrm{Y}_{\mathrm{Kt}}+\mathrm{Y}_{\mathrm{Lt}}$ (or on total expenditures $\mathrm{C}_{\mathrm{t}}+\mathrm{I}_{\mathrm{t}}$, which in a closed economy setting is equivalent), with an implicit production tax rate $T_{p t}=T_{p t} /\left(Y_{t}-T_{p t}\right)$. Under this assumption, the total tax rates on capital and labor (including production taxes) $\mathrm{T}_{\mathrm{Kt}}$ and $\mathrm{T}_{\mathrm{Lt}}$ are given by: ${ }^{48}$

$$
\begin{align*}
& \mathrm{T}_{\mathrm{Kt}}=1-\left(1-\mathrm{T}_{\mathrm{Kt} 0}\right) /\left(1+\mathrm{T}_{\mathrm{pt}}\right)=\left(\mathrm{T}_{\mathrm{Kt0}}+\mathrm{T}_{\mathrm{pt}}\right) /\left(1+\mathrm{T}_{\mathrm{pt}}\right)  \tag{A.16}\\
& \mathrm{T}_{\mathrm{Lt}}=1-\left(1-\mathrm{T}_{\mathrm{Lt} 0}\right) /\left(1+\mathrm{T}_{\mathrm{pt}}\right)=\left(\mathrm{T}_{\mathrm{Lt} 0}+\mathrm{T}_{\mathrm{pt}}\right) /\left(1+\mathrm{T}_{\mathrm{pt}}\right) \tag{A.17}
\end{align*}
$$

[^77]The corresponding series for $T_{K t}$ and $T_{L t}$ are reported on col. (12)-(13) of Table A9. In the 2000s, the labor tax rate was about $55 \%$, while the capital tax rate was about $35 \%$. If one deducts from labor taxes the fraction of social contributions financing replacement income, then the labor tax rate drops to about $30 \%$ (see col. (14)). ${ }^{49}$ It seems more justified to treat replacement income as part of (augmented) labor income (this is what we do in our theoretical and simulated models), so this second definition of the aggregate labor tax rate is more relevant, e.g. for the purpose of comparison with the capital tax rate.

Our methodological choice of treating production taxes as broad factor income taxes is not entirely innocuous, but seems like the most reasonable option, given data limitations. In practice, production taxes (in the D2 ESA 1995 national accounts classification sense) are a complex mixture of broad factor income taxes (or expenditure taxes) and pure consumption taxes. ${ }^{50}$ Estimating their exact tax incidence would involve complicated open economy and asset pricing issues, and falls well beyond the scope of this research. In case a fraction of production taxes falls purely on consumption, then the formulas for $\mathrm{T}_{\mathrm{kt}}$ and $\mathrm{T}_{\mathrm{Lt}}$ would still be valid, but they should be interpreted as averages over the different final uses of income: whether their income comes from capital or from labor, individuals would face higher tax rates when they use their income to purchase consumption goods than when use it purchase investment goods. In a homogenous good model, there would in effect be a price $p_{t}=1$ when the single good is purchased as a capital good, and a price $p_{t}^{\prime}=1+\mathrm{t}$ when it is purchased as a consumption good, where t measures the fraction of production taxes falling on consumption, expressed in equivalent consumption tax rate. ${ }^{51}$ E.g. in the 2000s, with full shifting of production taxes on consumption prices, the capital tax rate would be equal $\mathrm{T}_{\mathrm{Kt0}}=25 \%$ when capital income is saved, equal to $\mathrm{T}_{\mathrm{Kt1}}>35 \%$ when capital income is consumed, with a weighted average (using aggregate savings rate) equal to $T_{K t}=35 \%$. In practice less than half of total D2 revenues can be viewed as falling on consumption, so the effect would even be less strong. The overall impact on long run capital accumulation (in effect we are under-estimating the quantity of investment goods that savings can buy, whether savings come from capital or labor income) would be relatively small. In any case, this would simply lead us to revise downwards our estimate of

[^78]the residual capital gain terms in our wealth accumulation equation (see below), with no impact on $W_{t}$, and on the rest of our analysis. ${ }^{52}$

Table A10: disposable income \& savings (1896-2008)

We define personal disposable income $\mathrm{Y}_{\mathrm{dt}}$ as follows:

$$
\begin{equation*}
Y_{d t}=Y_{t}-T_{t}+Y_{R t}+Y_{K g t} \tag{A.18}
\end{equation*}
$$

l.e. disposable income equals national income minus taxes plus government monetary transfers (replacement income) plus net government interest payments. ${ }^{53}$ We find that disposable income $Y_{d t}$ was about 95\% of national income $Y_{t}$ around 1900-1910, dropped to about $80 \%$ by 1950 , and stabilized around $70 \%$ in the 1990 s-2000s (see Table A10, col. (1)). This simply comes from the fact that taxes currently represent about $50 \%$ of national income, while transfers are only $20 \%$ of national income (see Table A9). Note however that it is somewhat arbitrary to include only monetary government transfers in the definition of disposable income. In-kind government transfers, as recorded by national accounts, make almost $20 \%$ of national income in the 1990s-2000s (see Table A9, col. (16)), mostly in the form of free health and education services provided by the government. If in-kind transfers were added to the definition of disposable income, then disposable income in the 1990s-2000s would be about $90 \%$ of national income, i.e. roughly the same level as one century ago. ${ }^{54}$ This is why in this research we prefer to use national income rather than disposable income as the proper income denominator when we compute aggregate wealth-income ratios or inheritance-income ratios.

Disposable income $Y_{d t}$ can be broken into three terms:

$$
\begin{equation*}
Y_{d t}=Y_{K d t}+Y_{L d t}+Y_{R d t} \tag{A.19}
\end{equation*}
$$

[^79]With:
$Y_{\text {Kdt }}=$ after-tax capital income ${ }^{55}$
$Y_{\text {Ldt }}=$ after-tax labor income ${ }^{56}$
$Y_{\text {Rdt }}=$ after-tax replacement income ${ }^{57}$

We find that the share of after-tax capital income in disposable income has been relatively stable in the long run, albeit at somewhat higher levels in the early $20^{\text {th }}$ century ( $30 \%-35 \%$ ) than in the late $20^{\text {th }}$ century ( $20 \%-25 \%$ ), which resembles closely the evolution of the pretax capital share in national income. ${ }^{58}$ Because average tax rates on capital and labor have been fairly similar as a first approximation (once one takes away replacementincome payroll taxes), the tax system as a whole had a limited impact on the functional distribution. The main change from a long run perspective is the large rise of replacement income and the corresponding decline of labor income (see Table A10, col.(12)-(13)).

Note that we include net-of-depreciation corporate retained earnings in our definitions of after-tax capital income and disposable income. This seems like the most logical way to proceed: presumably retained earnings are in the interest of the owners of corporations (otherwise shareholders would opt for bigger dividends); as a first approximation they can be viewed as capital income that is immediately saved by shareholders and reinvested in the company. In general, this does not make a big difference in terms of levels. ${ }^{59}$ E.g. in

[^80]the 1990s-2000s, the total after-tax capital share in disposable income is about $24 \%-25 \%$, with non-retained-earnings capital income around $22 \%-23 \%$ and retained earnings around 1\%-2\% (and sometime negative) (see Table A10, col. (14)-(15)). But this can affect the trends. E.g. retained earnings were higher in the 1950s-1960s (typically $3 \%-4 \%$ of disposable income) than they are today (typically $1 \%-2 \%$ of disposable income), so that if one takes away retained earnings from capital income, then the after-tax capital share would appear to be larger in the 1990 s-2000s than in the 1950 s-1960s. ${ }^{60}$

Finally, we break down disposable income between consumption and savings:

$$
Y_{d t}=C_{t}+S_{t} \quad \text { (A.20) }
$$

With:
$\mathrm{S}_{\mathrm{t}}=$ private savings $=$ personal (household) savings + corporate retained earnings
$\mathrm{C}_{\mathrm{t}}=$ private consumption $=\mathrm{Y}_{\mathrm{dt}}-\mathrm{S}_{\mathrm{t}}$

For reasons explained above, we include net-of-depreciation corporate retained earnings in our definition of private savings. We find that private savings have generally fluctuated around $10 \%$ of national income over the 1896-2008 period, with the important exception of the reconstruction periods of the 1920s and the 1950s-1960s, when savings were significantly higher (in particular due to retained earnings). ${ }^{61}$ These unusually high savings rate during reconstruction periods, especially during the 1920s, must of course be related to the large rates of capital destructions observed during war years (see Table A10, col.

[^81](9)); we return to this when we estimate the accumulation equation for private wealth (see section A5 below). ${ }^{62}$

Col. (1) to (17) of Tables A11-A12: summary macro variables (1820-2008)

On Table A11 we report the main macro variables obtained from the previous tables (capital and labor shares, tax rates, savings rates). On Table A12 we report the decennial averages corresponding to these annual 1896-2008 series, which we complete by providing decennial averages estimates covering the 1820-1900 period.

As was already noted, available national accounts series prior to 1896 are relatively rudimentary. The $19^{\text {th }}$ century estimates reported on Table A12 for functional shares, tax rates and savings rates should be viewed as approximate and provisional. We proceed as follows.

Regarding capital and labor shares, there exists to our knowledge no estimate for $19^{\text {th }}$ century France, ${ }^{63}$ so we construct our own series using available wage indexes. I.e. the capital and labor shares $\alpha_{t}$ and 1- $\alpha_{t}$ reported on col.(3)-(4) of Table A12 for years 18201829, 1830-1839, etc., until 1890-1899 are computed by dividing the estimated nominal wage bill for each decennial period by the corresponding national income, and by anchoring our labor share series $1-\alpha_{t}$ to the 1900-1909 and 1910-1913 values coming from our annual series. ${ }^{64}$ Nominal wage bill estimates arere computed by multiplying the best available nominal wage index series by the relevant population index. ${ }^{65}$

[^82]We find that the labor and capital shares in (factor-price) national income have been relatively stable in the long run over the 1820-1913 period, but with large medium run variations. According to our estimates, the capital share gradually rose from about 30\%$35 \%$ in the 1820 s-1830s to as much as $45 \%$ in the 1850 s- 1860 s, then gradually declined to as little as $25 \%-30 \%$ around $1890-1900$, and finally rose again, up to about $35 \%$ in 1910-1913. Given the data limitations we face, these series should be interpreted with caution. In particular, it is difficult (if not impossible) to estimate precisely the extent to which available $19^{\text {th }}$ century wage indexes are representative of the whole workforce of the time. However the general pattern seems to be robust. In particular, all available wage series show that there was very little wage growth (if any) until the 1850s-1860s, in spite of the large growth in manufacturing output and total national income. We tried alternative series and methods, and we always find a large rise of the capital share between the 1820s-1830s and the 1850s-1860s. ${ }^{66}$ Similarly, all series indicate very rapid wage growth during the second half of the $19^{\text {th }}$ century (nominal wages almost doubled), with growth rates significantly larger than those of output and national income - thereby suggesting a marked decline in the capital share. Wage and output series also seem to indicate that the rebound of the capital share between 1900 and 1913 is statistically robust. ${ }^{67}$ Whether the

[^83]levels of capital shares estimated for the $19^{\text {th }}$ century (and particularly the very high levels obtained for the 1850 s-1860s) are also statistically robust, and can be compared to $20^{\text {th }}$ century levels in a meaningful way, is a more complicated issue. ${ }^{68}$

Regarding government taxes (col. (7)-(9) of Table A12), we simply assume an aggregate tax rate equal to $8.0 \%$ of national income throughout the $1820-1899$ period, i.e. approximately the same level as in our 1900-1913 annual series. ${ }^{69}$ For simplicity we also assume that this tax rate of $8.0 \%$ fell proportionally on capital and labor income throughout the 1820-1899 period. ${ }^{70}$ We make a similar stability assumption regarding government transfers. ${ }^{71}$

Regarding savings (col.(12)-(14) of Table A12), we computed average decennial private savings rates from the investment series constructed by Bourguignon and Levy-Leboyer (1985). These series do not allow to differentiate between personal savings and corporate retained earnings, so the private and personal savings rates reported on Table A12 for the 1820-1899 period are the same. We find that private savings have been relatively stable around $8 \%-10 \%$ of national income during the $19^{\text {th }}$ century. ${ }^{72}$

[^84]We also report on Tables A11 and A12 estimates of average rates of return on private wealth. In order to compute the pre-tax return on private wealth $r_{t}$, one simply needs to divide the primary capital share $\alpha_{t}^{*}$ in (factor-price) national income by the wealth-income ratio $\beta_{t}=W_{t} / Y_{t}$ :

$$
\begin{equation*}
r_{t}=\alpha_{t}^{*} / \beta_{t} \tag{A.21}
\end{equation*}
$$

The after-tax rate of return to private wealth $r_{t}$ is similarly defined as the ratio between the after-tax capital share $\alpha_{\mathrm{dt}}{ }^{*}$ in national income and the wealth-income ratio $\beta_{\mathrm{t}}$ :

$$
\begin{equation*}
r_{\mathrm{dt}}=\alpha_{\mathrm{dt}}{ }^{*} / \beta_{\mathrm{t}}=\left(1-\mathrm{T}_{\mathrm{Kt}}{ }^{*}\right) \mathrm{r}_{\mathrm{t}} \tag{A.22}
\end{equation*}
$$

With a wealth-income ratio $\beta_{t}$ equal to $600 \%$ and a capital share $\alpha_{t}{ }^{*}$ equal to $30 \%$, we would get a pre-tax rate of return $r_{t}$ equal to $5 \%$. If we compute a simple arithmetic average of our $r_{t}$ estimates over the 1820-2009 period, we find an average pre-tax return equal to $6.8 \%$ (see Table A12, col.(6)). This reflects the fact that on average over the two centuries wealth-income ratios have actually been less than $500 \%$ (due to the low ratios which prevailed during most of the $20^{\text {th }}$ century), and capital shares have actually been (slightly) above $30 \%$. The average pre-tax rate of return was equal to $5.9 \%$ during the 1820-1913 period and 7.7\% during the 1913-2009 period, again reflecting the lower average wealthincome ratios prevailing in the $20^{\text {th }}$ century. Within the $1913-2009$ period, the large variations in the wealth-income ratios have generated large variations in pre-tax rates of return: $r_{t}$ was as large as $10 \%$ both during the 1920 s and the 1950 s (see Figure A12). Taxes played a relatively small role during the $19^{\text {th }}$ century and a much larger role in the $20^{\text {th }}$ century: on average, the after-tax rate of return $r_{d t}$ appears to be equal to $5.4 \%$ both during the 1820-1913 period and the 1913-2009 period. Over the past thirty years (19792009), the pre-tax return $r_{t}$ was $6.9 \%$, while the after-tax return $r_{d t}$ was $4.3 \%$ (see Table A12, col. (11)). ${ }^{73}$

[^85]To the extent that asset prices rise as much as consumer prices in the long run (see section A5 below), the rates of return $r_{t}$ and $r_{d t}$ are better thought as real rates of return. In the short run and medium run, however, large variations in asset prices relatively to consumer prices often generate large capital gains and losses, which need to be added to the flow returns $r_{t}$ and $r_{d t}$ in order to compute the full real returns to private wealth. Warinduced capital destructions also need to be taken into account. On Table A12, we use the (imperfect but consistent) real rates of capital gains $q_{t}$ and war destructions $d_{t}$ estimated in section A5 below in order to compute augmented after-tax rates of return $r_{d t}{ }^{*}=r_{d t}+q_{t}+d_{t}=$ ( $1-\mathrm{T}_{\mathrm{Kt}}{ }^{*} \mathrm{r}_{\mathrm{t}}+\mathrm{q}_{\mathrm{t}}+\mathrm{d}_{\mathrm{t}}{ }^{74}$ The impact on century-long averages is small; but the impact on decennial averages can be extremely substantial, both during the chaotic world war periods and during peacetime asset price boom periods such as the 2000s. Over the 1913-1949, the after tax flow return $r_{d t}$ was $6.4 \%$, but the augmented return $r_{d t}{ }^{*}=r_{d t}+q_{t}+d_{t}$ was only $1.9 \%$, due to large capital losses and destructions. Conversely, in the 2000-2009 decade, the after tax flow return $r_{d t}$ was only $3.5 \%$, but the augmented return $r_{d t}{ }^{*}$ was as high as $7.7 \%$, due to large capital gains. Note however that if we take averages over several decades the size of capital gains and losses is usually much smaller than the flow return itself (except naturally during destruction periods). E.g. over the past 30 years (1979-2009), the after tax flow return $r_{d t}$ was $4.3 \%$, and the augmented return $r_{d t}{ }^{*}$ was $5.3 \%$ (see Table A12, col. (15)-(17)).

Capital gains and losses seem to play a smaller role in explaining the 1820-1913 evolution of aggregate rates of returns, which is primarily driven by the relatively large movements of the capital share (and to a lesser extent of the wealth-income ratio). According to our computations, the aggregate rate of return $r_{t}$ rose from $5 \%-6 \%$ in the 1820 s-1830s to over $7 \%$ during the 1850s-1860s (when the profit share reached its record level), then declined to little more than 4\% during the 1870-1900 period, and then rose again to 5\%-6\% at the eve of World War 1 (see Table A12, col. (6)). The exact levels we obtain for these $19^{\text {th }}$ century rates of return are obviously fragile, given the data limitations of the time (see above); however the general pattern seems to be relatively robust, and consistent with a number of other data sources. ${ }^{75}$

[^86]These historical rates of return, the role they have played in the wealth accumulation and transmission process, and the role they might be playing in the future, are further analyzed in the working paper (see especially section 6) and in Appendix D.

## A.4. Supplementary series on the structure of private wealth $\mathbf{W}_{\mathbf{t}}$ (Tables A13-16)

Detailed annual series on the structure of private wealth $W_{t}$ in France over the 1970-2009 period (using official national wealth accounts) are reported on Tables A13 to A15. Available pre-1970, non official estimates of national and private wealth are reported on Table A16. In section A5 below we use these estimates together with savings series in order to estimate the private wealth accumulation equation and to construct continuous private wealth series. Here we describe how Tables A13 to A16 were constructed.

Table A13: private wealth vs government wealth (1970-2009)

All series reported on Tables A13-A15 come directly from official Insee-Banque de France balance sheets. ${ }^{76}$ We report values expressed as fractions of national income $Y_{t}$ (or other aggregates). ${ }^{77}$

On Table A13 we report the following basic decomposition of private wealth $W_{t}$ :

$$
\begin{equation*}
W_{t}=K_{p t}+A_{p t}-L_{p t} \tag{A.23}
\end{equation*}
$$

With: $\mathrm{K}_{\mathrm{pt}}=$ tangible (non-financial) assets of the personal sector ${ }^{78}$
$A_{p t}=$ financial assets of the personal sector

[^87]We find that the total market value of tangible assets owned by French households was relatively stable around $200 \%-220 \%$ of national income between the early 1970s and the late 1990s, and then nearly doubled during the 2000s (see Table A13, col. (2)). Note that the decomposition of personal tangible assets into housing tangible assets (residential real estate) and non-housing tangible assets (typically business assets owned by the selfemployed for conducting their unincorporated production activity: non-residential real estate, commercial dwellings, structures, equipment, land, etc.) has also changed a lot over the period. ${ }^{79}$ The rise of personal financial assets was more gradual, from about $100 \%$ of national income in the 1970s and early 1980s to about $150 \%$ in the 1990 s and over $200 \%$ in the 2000 s. Household debt also rose gradually from $20 \%-30 \%$ of national income in the 1970s-early 1980s to $40 \%-50 \%$ in the 1990s and $60 \%-70 \%$ in the 2000s. Net private wealth $W_{t}$ rose from $280 \%-300 \%$ of national income in the 1970s-early 1980s to $330 \%-350 \%$ in the 1990s and over 500\% in the 2000s (see Table A13, col. (1)-(4)).

We also report on Table A13 the same decomposition for government wealth $\mathrm{W}_{\mathrm{gt}}$ :

$$
\begin{equation*}
W_{g t}=K_{g t}+A_{g t}-L_{g t} \tag{A.24}
\end{equation*}
$$

With: $\mathrm{K}_{\mathrm{gt}}=$ tangible (non-financial) assets of the government sector ${ }^{80}$
$A_{g t}=$ financial assets of the government sector
$L_{g t}=$ financial liabilities of the government sector

We find that net government wealth $\mathrm{W}_{\mathrm{gt}}$ has always been (slightly) positive and trendless during the 1970-2009 period, usually around $20 \%-40 \%$ of national income, in spite of the large rise of government debt, from $30 \%-50 \%$ of national income in the 1970s-1980s to $60 \%-80 \%$ in the 1990s and $90 \%-100 \%$ in the late 2000s. This is because government tangible and financial assets have always been larger than government debt, and rose from about $80 \%$ of national income in the 1970s to $130 \%-140 \%$ in the 2000s (see Table A13, col. (5)-(8)). The value of government tangible assets (administrative buildings, public schools and hospitals, etc.), as estimated by national accounts statisticians on the basis of observed market values for land and similar buildings, has always been larger than the

[^88]value of government financial assets. The long term rise of government tangible assets must naturally be related to the long term rise of the government sector share in national income and employment. ${ }^{81}$ The value of government financial assets did not decline significantly in the recent past, in spite of the large privatization waves of the late 1980s and 1990s. ${ }^{82}$

We also report on Table A13 the same decomposition for national wealth $W_{n t}$, which we define as the sum of private wealth $W_{t}$ and government wealth $W_{g t}$ :

$$
\begin{equation*}
\mathrm{W}_{\mathrm{nt}}=\mathrm{W}_{\mathrm{t}}+\mathrm{W}_{\mathrm{gt}} \tag{A.25}
\end{equation*}
$$

We find that private wealth has always represented the vast majority of national wealth throughout the 1970-2009 period: about 85\%-90\% during the 1970s-1980s, $90 \%-95 \%$ during the 1990s-2000s (see Table A13, col. (13)-(14)).

Table A14: corporate wealth and net foreign asset position (1970-2009)

On Table A14 we report supplementary data on the structure of corporate assets and on net foreign asset position. In principle this should be useless for our purposes: foreign assets were already counted in private wealth $\mathrm{W}_{\mathrm{t}}$ and government wealth $\mathrm{W}_{\mathrm{gt}}$ (we simply isolate them on Table A14 for illustrative purposes), and in theory the net worth of corporations should simply be equal to their equity value, which was also already counted in the balance sheets of the personal and government sector. However in practice there are many reasons why Tobin's $Q$ ratio might differ from $100 \%$, and it is useful to briefly

[^89]discuss how this might bias our private wealth estimates (and therefore our economic inheritance flow series).

We report on Table A14 the value of corporate net worth, defined according to the standard definition, and compare it to corporate equity value, in order to compute Tobin's Q ratio:

$$
\begin{align*}
\mathrm{NW}_{\mathrm{ct}} & =\mathrm{K}_{\mathrm{ct}}+\mathrm{A}_{\mathrm{ct}}-\mathrm{L}_{\mathrm{ct}}^{\mathrm{d}}  \tag{A.26}\\
\mathrm{Q} & =\mathrm{L}_{\mathrm{ct}}^{\mathrm{e}} / \mathrm{NW}_{\mathrm{ct}} \quad(\mathrm{~A} .27) \tag{A.27}
\end{align*}
$$

With: $\mathrm{NW}_{\mathrm{ct}}=$ net worth of the corporate sector (non-financial + financial) ${ }^{83}$
$\mathrm{K}_{\mathrm{ct}}=$ tangible (non-financial) assets of the corporate sector
$\mathrm{A}_{\mathrm{ct}}=$ financial assets of the corporate sector
$L_{c t}{ }^{d}=$ financial (non-equity) liabilities of the corporate sector
$\mathrm{L}_{c t}{ }^{\mathrm{e}}=$ equity value of the corporate sector ${ }^{84}$
$\mathrm{Q}=\mathrm{L}_{\mathrm{ct}}{ }^{\mathrm{e}} / \mathrm{NW}_{\mathrm{ct}}=$ ratio between corporate equity value and corporate net worth

We find that Tobin's Q ratio has been less than 100\% throughout the 1970-2009 period: it was about $60 \%$ in the early 1970 s, went as low as $30 \%-40 \%$ in the late 1970s-early 1980s, and stabilized around $70 \%-80 \%$ in the 1980s-1990s (see Table A14, col. (7)). As a consequence, if we compute net corporate wealth, defined as net worth minus equity value, which by definition should be equal to zero in case Tobin's $Q$ was exactly equal to $100 \%$, we find that net corporate wealth was positive throughout the 1970-2009 period. If we express net corporate wealth as a fraction of national wealth (defined above as the sum of private wealth and government wealth), we find that the value of net corporate wealth was the equivalent of about $20 \%-25 \%$ of national wealth throughout the 1970-2009 period (see Table A14, col.(8)).

[^90]In this research we certainly do not intend to solve the complex issue of Tobin's Q ratios and balance sheets measurement errors and statistical discrepancies. For our purposes the key question is the following: should we raise our national wealth and private wealth estimates by about $20 \%-25 \%$ ? Or is our private wealth concept $W_{t}$ (as defined above) the best available approximation that one should use in order to compute the economic inheritance flow? Of course there are lots of reasons why Tobin's $Q$ ratios might differ from $100 \%$ : equity pricing is a notoriously complicated and uncertain business, and corporate net worth (book value) is often a poor guide to evaluate future profit prospects. Given that we care about the market value of wealth (inheritance is valued at the asset market prices of the day), we should not care too much as to whether Tobin's $Q$ is momentarily above or below $100 \%$. However it is a bit puzzling that $Q$ ratios appear to be systematically below $100 \%$, including during time periods which are generally viewed as stock market booms and equity overpricing. For instance, the Q ratio appears to be equal to $86 \%$ on January $1^{\text {st }}$ 2000: this is more than in every other year, but this is still below $100 \% .{ }^{85}$

The reason why we finally decided not to make any correction to our private wealth $W_{t}$ series is the following. The most plausible explanations as to why Tobin's Q is systematically below $100 \%$ are corporate tangible assets overpricing on the one hand, and control rights valuation on the other hand; in both cases, this is not relevant for our purposes.

The corporate tangible assets overpricing story has been recently advocated by Wright (2004) using U.S. data. ${ }^{86}$ Many tangible assets owned by corporations (e.g. the Paris headquarters of a large financial firm or the specific machinery and infrastructure used by

[^91]manufacturing or utilities company) are difficult to value: readily available market prices are often missing, so that national accounts statisticians (as well as private accountants) generally use a mixture of perpetual inventory methods and market valuation methods in order to put a market price on these assets. Wright argues that on average this might lead to systematic overvaluation of corporate tangible assets (and therefore of corporate net worth), e.g. because rates of capital depreciation on these assets are underestimated. If this is the explanation as to why $Q$ ratios are below $100 \%$, then we should definitely not correct upwards our national wealth and private wealth estimates. ${ }^{87}$

The control rights valuation story is the following. Estimates of aggregate equity value are based upon observed stock market prices, which typically reflect prices for small marginal transactions. In practice, one typically needs to pay a premium as large as $20 \%-25 \%$ in order to purchase sufficient stock to take the control of a corporation, e.g. in order to liquidate its book value. This could mechanically explain why Tobin's $Q$ ratios might be structurally lower than 100\%. More generally, the fact that equity values are lower than book values might reflect the fact that shareholders have imperfect control over corporations (and in particular over future profit streams): depending on the country and the specific time period and institutional set-up, other stake holders (such as wage earners or the broader public opinion) might have a say on how corporations should behave, shareholders might have various beliefs about future tax policies or expropriation threats, etc. ${ }^{88}$ But whatever the exact story might be, we feel that it is justified for our purposes to use our market value based definition of private wealth $W_{t}$ (inheritance is valued at prevailing market prices). For other purposes, e.g. if one wants to compute the fundamental economic value of personal wealth, one might prefer to re-attribute the corporate value that is not included in marginal stock market valuation to the ultimate

[^92]owners of corporations, and raise personal wealth accordingly (see e.g. Atkinson (1972)). ${ }^{89}$

We also report on Table A14 the value of net foreign assets $W_{F t}$, defined as the difference between total foreign financial assets owned by French residents $F A_{t}$ and and total French financial assets owned by foreign residents $F L_{t}$. The net foreign asset position of France appears to have been (slightly) positive during most of the 1970-2009 period, except in 1990-1994 and 2009, when it was (slightly) negative. Most importantly, it has always been extremely small. Expressed as fraction of national wealth, the value of net foreign assets has been in the $-1 \%$ to $+5 \%$ range throughout the 1970-2009 period (see Table A14, col. (14)). ${ }^{90}$ Note however that gross asset positions appear to have risen enormously in recent decades (due to financial globalization): in the 1970s, gross capital foreign asset positions were around $30 \%$ of national income; in the 2000 s, they were around $300 \%$ of national income (see Table A14, col. (9)-(13)). This is qualitatively and quantitatively consistent with the income account data reported on Table A5 above.

## Tables A15a \& A15b: composition of private wealth (1970-2009)

On Tables A15a-A15b, we report detailed series describing the changing composition of private wealth, using asset categories that can be compared to the categories available in bequest and gift tax returns. Values are expressed as a fraction of national income on Table A15a, and as a fraction of private wealth on Table A15b.

We find that the value of housing assets (residential real-estate tangible assets, net of mortgage debt) has increased significantly over the period, from about $30 \%$ of total private wealth in the 1970s to about $50 \%$ in the 2000s. The value of non-housing personal tangible assets, which mostly consist of business assets owned by the self-employed for conducting their unincorporated production activity (non-residential real estate, commercial

[^93]dwellings, structures, equipment, land, etc.), has declined enormously, from over 35\% of private wealth in the 1970s to about 10\% in the 2000s. This largely reflects the sharp decline of self employment in France during the past 40 years. ${ }^{91}$ The share of financial assets in private wealth was about $35 \%$ in the 1970s and gradually rose over $50 \%$ by 2000, and went down to about $40 \%$ during the 2000s, due to the housing market boom (see Table A15b, col. (2), (5) and (6)).

The composition of financial assets has also changed in important ways since 1970. The share of equity assets has always been around one third of total financial assets (with public equity and mutual funds gradually taking over private equity), and the non-equity share has always been around two thirds. ${ }^{92}$ This reflects the fact private individuals in France have limited direct stock market ownership. Within non-equity assets, one observes a very large rise of life-insurance assets, which made only $2 \%$ of private wealth in the 1970s, up to about $15 \%$ in the 2000s, i.e. about a third of total financial assets (see Table A15b, col. (7)-(12)).

The large development of life insurance in France has certainly been encouraged by its very favourable tax treatment. In particular, life insurance has always been (almost) entirely exempt from bequest and gift tax: the corresponding wealth can be transmitted tax free to children, surviving spouses and other beneficiaries. Note also that in France life insurance is often used as a long term, old-age saving vehicle, in the absence of explicit

[^94]pension funds. ${ }^{93}$ In principle, we should make a correction for the annuitized fraction of lifeinsurance assets, i.e. for the fact that a fraction of what is counted as life-insurance assets cannot be bequeathed at death. However this annuitized fraction is difficult to estimate, and in any case appears to be relatively small (at most $20 \%$ ). ${ }^{94}$ Life-insurance assets currently represent about $15 \%$ of aggregate private wealth $W_{t}$, so this implies that the nonbequeathable fraction of aggregate private wealth $W_{t}$ is at most $3 \%$. In addition, note that we did not attempt to make corrections for the fact that a number of bequeathable assets are not included in our private wealth $W_{t}$ estimates. In particular, consumer durables (such as cars or furnitures), which usually represent less than $5 \%$ of total wealth, ${ }^{95}$ are excluded from the Insee-Banque de France balance sheets, ${ }^{96}$ and therefore are also excluded from our private wealth $W_{t}$, in spite of the fact that durables are in principle subject to the estate tax. Because these two corrections terms (annuitized fraction of life insurance assets, consumer durables) are small, hard to estimate with precision, and tend to compensate one another, we feel that it is more reasonable not to make any explicit correction at this stage, and to leave these issues for future research. ${ }^{97}$

[^95]We also report on Table A15b estimated fractions of assets that are subject the bequest and gift tax. These estimates are used in Appendix B1 in order to upgrade the fiscal inheritance flow series; they were computed on the basis of estate tax law and of asset composition observed in estate tax returns. ${ }^{98}$

Table A16: Raw national wealth estimates in France (1820-2008)

On Table A16 we report the various non-official, pre-1970 national and private wealth estimates that we used in this research (for comparison purposes we also report official estimates for 1978, 1990 and 2008). Pre-1970 national and private wealth estimates are more rudimentary and offer fewer (and less homogeneous) break downs than post-1970 Insee-Banque de France balance sheets, so we only report the decomposition between private and government wealth, as well as estimates of the share of foreign assets in private wealth.

As we explain the working paper (see section 3.2), national and private wealth estimates for the 1820-1913 are plentiful and relatively reliable. The national and private wealth concepts used by the economists of the time are broadly similar to the concepts of $\mathrm{W}_{\mathrm{nt}}$ and $W_{t}$ that we defined using modern, post-1970 official balance sheets. In particular, $19^{\text {th }}$ century and early $20^{\text {th }}$ century economists defined aggregate private wealth ("fortune privée") as the market value of all tangible and financial assets owned by private individuals, minus their financial liabilities. They relied mostly upon the decennial censuses of tangible assets organized by the tax administration (the tax system of the time relied extensively on the property values of real estate, land and business assets, so such censuses played a critical role). They took into account the growing stock and bond market capitalisation and the booming foreign assets, and they usually explained in a precise and careful way how they made all the necessary corrections in order to avoid all forms double counting. The most sophisticated estimates, e.g. those of Colson (1903), compare explicitly the equity value of corporations obtained from stock market capitalization (deducting cross holdings), to the book value of corporations obtained by summing up the value of tangible assets (minus debt), and find similar results using both methods (i.e. they find that Tobin's Q ratios were close to $100 \%$ on average). The most important point to be careful about is the following: one should use only the national wealth estimates that were

[^96]explicitly based upon wealth-census-type methods, and ignore estimates based upon estate-multiplier-type computations. ${ }^{99}$ All estimates reported on Table A16 are based upon wealth-censuses methods.

For 1913, we take the reference estimate due to Colson, with aggregate private wealth of 297 billions old francs, including an estimated 41 billions in foreign assets. ${ }^{100}$ For 1896, there are variations across authors within the 190-230 billions range, and we take an average estimate of 205 billions. ${ }^{101}$ For earlier decades (1820-1829, ..., 1880-1889), the confidence interval between the various authors is usually less than $10 \%$, and we report on Table A16 the average estimates of private wealth available in the literature, from about 62 billions old francs in the 1820s to about 195 billions old francs in the 1880s. ${ }^{102}$ The published estimates usually include separate computations for government wealth (government tangible and financial assets, minus government debt), showing that government wealth was a positive but small fraction of national wealth throughout the 1820-1913 period: between $2 \%$ and 5\%, i.e. private wealth always represents $95 \%-98 \%$ of national wealth (see Table A16, col. (8)-(9))). ${ }^{103}$ All estimates also show a large and gradual rise of foreign assets, from about $2 \%-3 \%$ of aggregate private wealth in the 1820s1840s to about $10 \%$ in the 1860 s-1870s and almost $15 \%$ in 1900-1913 (see Table A16, col.(3)). ${ }^{104}$

[^97]The 1914-1969 period is the most problematic one from the viewpoint of national and private wealth estimates in France. This was a chaotic time for wealth (war destructions, large inflation, wide variations in real estate and stock prices, not to mention the fact that large segments of banking and manufacturing sector were nationalized in 1945). This certainly discouraged the economists of the time from pursuing the private wealth computations that were so popular until 1913. We used only two estimates of private and national wealth over the 1914-1969 period. Both are based upon methods and concepts that are broadly similar to the 1820-1913 and 1970-2009 estimates: one for year 1925 due to Colson (1927), and one for year 1954 due to Divisia, Dupin and Roy (1956). Both are reported on Table A16.

The advantage of the 1925 estimate that it was constructed by Colson using the same methods and concepts as his estimates for years 1898 and 1913. One central difficulty with this period is that asset prices declined significantly relatively to consumer prices between 1913 and 1925, with large movements in the relative prices of various assets. ${ }^{105}$ Colson carefully explains how he computed the market value of 1925 private wealth $W_{t}$ using the asset prices prevailing in 1925 for the various assets, which is what we want. ${ }^{106}$ Colson uses the same method to estimate the net market value of government wealth $\mathrm{Wg}_{\mathrm{gt}}$, which for the only time in our long run series appears to be negative in 1925: the French government accumulated so much public debt during the World War 1 and the early 1920s that by 1925 the value of government debt significantly exceeded the value of government tangible and financial assets (see Table A16, col. (4)-(6)). According to these computations, private wealth $W_{t}$ according to these computations was equal to $293 \%$ of national income, but national wealth $\mathrm{W}_{\mathrm{nt}}=\mathrm{W}_{\mathrm{t}}+\mathrm{W}_{\mathrm{gt}}$ was equal to $241 \%$ of national income (see Table A16, col. (10)-(14)). This 1925 Colson estimate could possibly be improved by returning to the raw statistical material of the time. ${ }^{107}$ But at this stage one can consider

[^98]that this is relatively reliable and well documented estimate - and in any case by far the best available estimate for the interwar period.

Similarly, the advantage of the 1954 estimate is that Divisia-Dupin-Roy use the same methods and concepts as Colson, and make a systematic comparison with the 1913 Colston estimates for the different types of assets. Also, Divisia-Dupin-Roy are very careful at distinguishing between market values and book values (including for unincorporated businesses). The estimate that we report on Table A16 for private wealth $W_{t}$ corresponds to their market value of private wealth (i.e. evaluated at the asset prices prevailing in 1954). ${ }^{108}$ They also provide interesting estimates of government wealth $\mathrm{W}_{\mathrm{gt}}$, which unlike in 1925 was significantly positive in 1954: this comes from the fact that public debt vanished in the immediate postwar period (due to inflation), while at the same time government tangible and financial assets rose substantially (due to 1945 nationalisation policy). In effect, the government was the owner of substantial segments of the French corporate sector in the 1950s. According to the Divisia-Dupin-Roy estimates, the share of government wealth $\mathrm{W}_{\mathrm{gt}}$ in national wealth $\mathrm{W}_{\mathrm{nt}}=\mathrm{W}_{\mathrm{t}}+\mathrm{W}_{\mathrm{gt}}$ was as large as $32 \%$ in 1954 , while the share of private wealth $W_{t}$ was only $68 \%$ (see Table A16, col. (8)-(9)). ${ }^{109}$ It took several decades for government debt to build up again (and also for corporate privatizations to occur) and finally for the government share in national wealth to return to about $5 \%$ in the 1990s-2000s, i.e. about the same level as during the 1820-1913 period (see Figure A14).

We also borrowed to Divisia et al (1956) their estimates of physical capital destructions during both world wars. After a careful review of the various existing computations on wartime physical destructions (real estate, structures, equipment, machinery, etc.), Divisia-Dupin-Roy come with the conclusion that total capital destructions represented the equivalent of about $11 \%$ of 1913 aggregate private wealth $W_{t}$ during World War 1, and the

[^99]equivalent of about $22 \%$ of 1913 aggregate private wealth $W_{t}$ during World War $2 .{ }^{110}$ We also added to these physical destruction numbers available estimates for foreign assets losses during World War 1 (typically, Russian bonds repudiation), which to some extent can be assimilated capital destruction. Total foreign assets losses during World War 1 appear to be as large as physical capital destructions strictly speaking: the equivalent of about $12 \%$ of 1913 aggregate private wealth. ${ }^{111}$ Overall, total private wealth destructions (including foreign assets losses) amount to about $23 \%$ of 1913 aggregate private wealth $W_{t}$ during World War 1, and about 22\% during World War 2. We use these estimates when we compute the private wealth accumulation equation below. ${ }^{112}$

How reliable are our aggregate private wealth estimates for the chaotic 1914-1969 period?
With our data we find that private wealth $W_{t}$ was $660 \%$ of national income $Y_{t}$ in 1913, $293 \%$ in $1925,203 \%$ in 1954 , and $289 \%$ in 1970 (see Table A16, col. (10)). We certainly do not pretend that the 1925 and 1954 numbers are perfectly comparable to the pre-1913 and the post-1970 numbers: the quantitative precision of such ratios should not be over-

[^100]estimated, especially in times of economic crises. However, there are several reasons to believe that these numbers provide a relatively accurate quantitative picture of changes in the wealth-income ratio (at least as a first approximation). First and foremost, as we show below, this 1913-1925-1954-1970 profile of the wealth-income ratio is broadly consistent with the aggregate accumulation equation for private wealth, i.e. with the savings rates coming from national income accounts and the (imperfect) asset price indexes at our disposal (see section A5 below). Next, our 1954 private wealth total is consistent with a number of independent computations that were made in France in the 1960s-1970s, at the time when Insee was starting to construct official balance sheets. ${ }^{113}$ Finally, it is reinsuring to see that economic inheritance flows that we obtain from our national wealth estimates are consistent with the fiscal inheritance flows, including during the 1914-1969 period. Note however that the gap between our fiscal and economic inheritance flow series is significantly larger in the 1920s-1930s and 1950s-1960s than in the pre-World War 1 and post-1970 period. ${ }^{114}$ If anything, this suggests that our wealth-income $W_{t} / Y_{t}$ for 1925 ( $293 \%$ ) and 1954 ( $203 \%$ ) are over-estimated, i.e. that aggregate private wealth was even lower than what the Colson-Divisia-Dupin-Roy computations indicate. In order to obtain the same economic flow-fiscal flow ratios as for the other periods, one would need to assume that the aggregate wealth-ration $W_{t} / Y_{t}$ was as low as $210 \%-230 \%$ in 1925 (instead of $293 \%$ ), and as low as $150 \%-170 \%$ in 1954 (instead of $203 \%$ ). ${ }^{115}$ Given the very large asset price movements of the time, and the data imperfections we face, this is certainly a possibility that cannot be excluded. However it is likely that the higher economic-fiscal flow ratios also reflect higher estate tax evasion during this period, and/or higher unmeasured

[^101]legal estate tax exemptions. ${ }^{116}$ So these alternative wealth-income ratios for 1925 and 1954 should probably be viewed as absolute lower bounds, and our Colson-Divisia-Dupin-Roy-based ratios should be viewed as more realistic and consistent. Available data does not allow us to push this analysis much further. Given that this (limited) residual uncertainty has little consequence for our overall long run empirical and theoretical analysis, we leave this issue for future work.

## A.5. Computation of the private wealth accumulation equation (Tables A17-A19)

On Tables A17-A19 we report the series resulting from the computation of the private wealth accumulation equation. We need to estimate such an accumulation equation in order to overcome the incompleteness of historical national wealth accounts and to obtain annual series for private wealth $W_{t}$ (especially regarding the data-poor 1914-1969 period). More generally, estimating such an accumulation equation in the long run offers an opportunity to assess the internal consistency between national income and wealth accounts, and also to test standard capital accumulation models. Here we describe how Tables A17-A19 were constructed. We start by describing the basic accumulation equations, and then explain how they were applied to the 1896-2008 period (annual series) and to the 1820-1913 period (decennial averages).

## A.5.1. Capital accumulation equation with no price inflation

In a world with no price inflation, the relationship between private wealth at the beginning of year $t\left(W_{t}\right)$, private savings during year $t\left(S_{t}\right)$ and private wealth at the beginning of year $t+1$ (i.e. end of year $t)\left(W_{t+1}\right)$ would be straightforward:

$$
\begin{equation*}
W_{t+1}=W_{t}+S_{t} \tag{A.28}
\end{equation*}
$$

[^102]Dividing both terms by national income $\mathrm{Y}_{\mathrm{t}+1}$, and re-arranging the terms, one gets the following equation:

$$
\beta_{t+1}=W_{t+1} / Y_{t+1}=\left[\beta_{t}+s_{t}\right] /\left[1+g_{t+1}\right]
$$

I.e.:

$$
\begin{equation*}
\beta_{t+1}=\beta_{t}\left[1+s_{t} / \beta_{t}\right] /\left[1+g_{t+1}\right] \tag{A.29}
\end{equation*}
$$

With: $\beta_{t}=W_{t} / Y_{t}=$ (private wealth)/(national income) ratio
$s_{t}=S_{t} / Y_{t}=$ savings rate (private savings as a fraction of national income)
$1+g_{t+1}=Y_{t+1} / Y_{t}=$ growth rate of national income between $t$ and $t+1$

Intuitively, equation (A.29) says that the wealth-income ratio $\beta_{t+1}>\beta_{t}$ iff $s_{t} / \beta_{t}>g_{t+1}$ (i.e. if $\beta_{t}$ $\left.<\mathrm{s}_{\mathrm{t}} / \mathrm{g}_{\mathrm{t}+1}\right)$. Note that $\mathrm{s}_{\mathrm{t}} / \beta_{\mathrm{t}}=\mathrm{S}_{\mathrm{t}} / W_{\mathrm{t}}$ is simply equal to private savings as a fraction of private wealth, which can be labelled "savings-induced wealth growth rate". E.g. if $s_{t}=10 \%$ and $\beta_{t}$ $=500 \%$, then $\mathrm{s}_{\mathrm{t}} / \beta_{\mathrm{t}}=2 \%$ : private savings during year t represent $2 \%$ of wealth at the beginning of year t , and therefore allow wealth to grow at $2 \%$ per year between t and $\mathrm{t}+1$. Intuitively, he wealth-income ratio rises if and only the savings-induce wealth growth rate exceeds the growth rate of national income. In case $s_{t}$ and $g_{t}$ are stationary (i.e. $s_{t}=s g_{t}=g$ ), then $\beta_{\mathrm{t}}$ converges toward a steady-state value $\beta^{*}=s / g$. E.g. if $s=10 \%$ and $g=2 \%$, then $\beta^{*}=$ $500 \%$. This is simply the standard Harrod-Domar formula (see working paper, section 5 ).

In order to clarify this interplay between income growth and wealth growth, it is useful to note $g_{t+1}{ }^{s}$ the savings-induced wealth growth rate between $t$ and $t+1$, and to rewrite equation (A.29) in the following manner:

$$
\begin{equation*}
\beta_{t+1}=\beta_{t}\left[1+g_{w s t+1}\right] /\left[1+g_{t+1}\right] \tag{A.30}
\end{equation*}
$$

With: $g_{w s t+1}=s_{t} / \beta_{t}=S_{t} / W_{t}=$ savings-induced growth rate of private wealth

## A.5.2. Capital accumulation equations with capital gains

Taking price inflation into account complicates the capital accumulation equation. We note $P_{t}$ the consumer price index (average consumer prices during year $t$ ), and $Q_{t}$ the asset price index (asset prices at the beginning of year $t$ ). In practice, we observe nominal national income $Y_{t}$ (measured at current market prices for consumer goods and investment
goods), nominal private wealth $W_{t}$ (measured at current market prices for assets) and nominal wealth/income ratios $\beta_{\mathrm{t}}=\mathrm{W}_{\mathrm{t}} / Y_{\mathrm{t}}$. The year-to-year variations of $\beta_{\mathrm{t}}$ generally reflect both relative volume effects (as determined by savings $S_{t}$ ) and relative price effects (as determine by the evolution by the relative asset vs goods price index $Q_{t} / P_{t}$ ). We do have (reasonably) good series on consumer price indexes $P_{t}$, which allow us to compute consumer price inflation $p_{t}$ and real growth rate of national income $g_{t}$ :
$1+p_{t}=P_{t} / P_{t-1}=$ consumer price inflation
$1+g_{t}=\left(Y_{t} / P_{t}\right) /\left(Y_{t-1} / P_{t-1}\right)=\left(Y_{t} / Y_{t-1}\right) /\left(1+p_{t}\right)=$ real growth rate of national income

However, we usually do not have good measures of the asset price index $Q_{t}$ : we do have all sorts of price series for various assets (real estate prices, stock prices, etc.), but it is very difficult to weight them properly, especially given the very large variations in asset price inflation over different types of assets (more on this below). If we know the evolution of $W_{t}$, then we can define an implicit asset price index $Q_{t}$ directly from the wealth accumulation equation:

$$
\begin{gathered}
W_{t+1}=\left(Q_{t+1} / Q_{t}\right)\left(W_{t}+S_{t}\right) \\
\text { I.e. } \quad W_{t+1}=\left(1+q_{t+1}\right)\left(1+p_{t+1}\right)\left(W_{t}+S_{t}\right)
\end{gathered}
$$

Dividing both terms of the equation by $\mathrm{Y}_{\mathrm{t}+1}$, and re-arranging the terms, one gets the following equation:

$$
\beta_{\mathrm{t}+1}=\left[1+\mathrm{q}_{\mathrm{t}+1}\right]\left[\beta_{\mathrm{t}}+\mathrm{s}_{\mathrm{t}}\right] /\left[1+\mathrm{g}_{\mathrm{t}+1}\right]
$$

I.e. :

$$
\begin{equation*}
\beta_{t+1}=\left[1+q_{t+1}\right] \quad \beta_{t}\left[1+s_{t} / \beta_{t}\right] /\left[1+g_{t+1}\right] \tag{A.31}
\end{equation*}
$$

With:
$1+\mathrm{q}_{\mathrm{t}+1}=\left(\mathrm{Q}_{\mathrm{t}+1} / \mathrm{P}_{\mathrm{t}+1}\right) /\left(\mathrm{Q}_{\mathrm{t}} / \mathrm{P}_{\mathrm{t}}\right)=$ asset price inflation relatively to consumer price inflation ${ }^{117}$

[^103]In case asset prices increase (or decrease) just as much as consumer prices, then $\mathrm{q}_{\mathrm{t}}=0 \%$, and equation (A.31) boils down to equation (A.29): capital accumulation involves pure volume effects, as determined by savings. However, in case wealth holders experience real capital gains ( $q_{t}>0$ ), then equation (A.31) says that the wealth-income ratio can increase even though there is little savings (i.e. even though $s_{t} / \beta_{t}<g_{t+1}$, providing that real capital gains are strong enough), and conversely in case of real capital losses ( $\mathrm{q}_{\mathrm{t}}>0$ ). ${ }^{118}$ Alternatively, one could view real unrealized capital gains or losses as capital income that is being saved at a $100 \%$ rate. I.e. if we note $Y_{K q t}=q_{t+1}\left(W_{t}+S_{t}\right)$ the real unrealized capital gains (or losses) made during year $t$, and if we define a corrected saving rate $s_{t}{ }^{*}=$ $\left(s_{t} Y_{t}+Y_{K q t}\right) / Y_{t}$, i.e. $s_{t}^{*}=s_{t}+q_{t+1}\left(\beta_{t}+s_{t}\right)$, then equation (A.31) can simply be rewritten as follows: $\beta_{t+1}=\beta_{t}\left[1+s_{t}^{*} / \beta_{t}\right] /\left[1+g_{t+1}\right]$.

In order to clarify this interplay between income growth and wealth growth, it is again useful to rewrite equation (A.31) in the following manner:

$$
\begin{equation*}
\beta_{t+1}=\beta_{t}\left[1+g_{w t+1}\right] /\left[1+g_{t+1}\right] \tag{A.32}
\end{equation*}
$$

Where $g_{w t+1}=\left(\mathrm{W}_{\mathrm{t}+1} / \mathrm{P}_{\mathrm{t}+1}\right) /\left(\mathrm{W}_{\mathrm{t}} / \mathrm{P}_{\mathrm{t}}\right)=\left(\mathrm{W}_{\mathrm{t}+1} / \mathrm{W}_{\mathrm{t}}\right) /\left(1+\mathrm{p}_{\mathrm{t}+1}\right)$ is the real (relative to CPI) total growth rate of private wealth between $t$ and $t+1$, which by construction can be decomposed into two terms, a savings effect and a capital gain effect:

$$
\begin{equation*}
1+g_{w t+1}=\left(1+q_{t+1}\right)\left(1+g_{w s+1}\right) \tag{A.33}
\end{equation*}
$$

With:

[^104]$g_{w t+1}=$ total real growth rate of private wealth between $t$ and $t+1$
$\mathrm{q}_{t+1}=$ capital-gain-induced growth rate of private wealth
$g_{w s t+1}=s_{t} / \beta_{t}=S_{t} / W_{t}=$ savings-induced growth rate of private wealth

## A.5.3. Applying the equations to France 1896-2009

We can now apply these equations to French series. On Table A17 we report the findings using two alternative methods. In method $\mathrm{n}^{\circ} 1$, we use total private savings (personal savings plus corporate retained earnings) in order to compute the accumulation equation. In method $\mathrm{n}^{\circ} 2$, we use personal savings alone. For reasons explained above (see section A3), we prefer method $\mathrm{n}^{\circ} 1$, which is conceptually more consistent. The corresponding savings rate used on Table A17 (col. (5) \& (11)) are borrowed from Table A10, col.(7)-(8). National income $Y_{t}$, expressed in 2009 euros using the CPI deflator, reported on Table A17 (col.(1)) is taken from Table A1, col.(1).

Regarding the 1970-2009 period, we observe the true annual series for the wealth-income ratio $\beta_{\mathrm{t}}$, thanks to the Insee-Banque de France private wealth series, so we do not need to estimate annual $\beta_{t}$ series. We can instead use the above equations in order to compute the implicit real rate of capital gains $q_{t}$ on an annual basis: ${ }^{119}$

$$
\begin{equation*}
1+q_{t}=\beta_{t}\left[1+g_{t}\right] / \beta_{t-1}\left[1+s_{t-1} / \beta_{t-1}\right]=\left(1+g_{w t}\right) /\left(1+g_{w s t}\right) \tag{A.34}
\end{equation*}
$$

For years 1971-2009, the $q_{t}$ series reported on col. (7) and (13) of Table A17 were obtained by applying mechanically equation (A.34). ${ }^{120}$ Unsurprisingly, the real rate of capital gains displays very large year-to-year variations, and capital gains effects often largely dominate savings effects for any given year. For instance the real rate of capital gains was strongly positive during the asset price boom of the mid-2000s (e.g. $\mathrm{q}_{\mathrm{t}}=+10.0 \%$ in 2005), and strongly negative the asset price collapse of the late 2000s (e.g. $\mathrm{q}_{\mathrm{t}}=-5.3 \%$ in 2009). ${ }^{121}$ However the important point is that these large year-to-year asset price variations tend to compensate each other if one looks at longer time periods. If we

[^105]compute the average over the 1970-2009, we find that the average rate of capital gains $\mathrm{q}_{\mathrm{t}}=+0.6 \%$, while the average rate of savings-induced real wealth growth was $\mathrm{g}_{\mathrm{wst}}=+3.2 \%$, thereby generating a total real wealth growth $g_{\mathrm{wt}}=+3.8 \%$ (see Table A17, line 1970-2009). That is, over the entire 1970-2009 period, savings explain $85 \%$ of total wealth growth, while capital gains explain only $15 \%$. When we do the same computations using personal savings (method $n^{\circ} 2$ ), then the average rate of capital gains rises to $\mathrm{q}_{\mathrm{t}}=+0.9 \%$, while the average rate of savings-induced real wealth growth was $g_{w s t}=+2.9 \%$. That is, the savings share in total wealth accumulation declines to $76 \%$, while the capital gains share rises to 24\% (see Table A17, line 1970-2009). This can be interpreted as saying that about one third of total capital gains over the 1970-2009 can be accounted for by corporate retained earnings (through additional investment and increased shareholder value). ${ }^{122}$

For the pre-1970 period, we observe the wealth-income ratio $\beta_{\mathrm{t}}$ only for a few isolated years (1896, 1913, 1925, 1954, 1970), and we want to use the equations above to construct annual series passing through these observations. We proceeded as follows. We first consider the 1954-1970 sub-period. We start from our estimated wealth-income ratio $\beta_{\mathrm{t}}=203 \%$ for 1954, and we compute the constant rate of capital gains $q_{t}$ over the 19551970 period which generates the observed wealth-income ratio $\beta_{\mathrm{t}}=289 \%$ for 1970 , given observed growth rates and savings rates over the 1955-1970 period and dynamic equations (A.32) and (A.33). We find that in order to reproduce the observed 1954-1970 pattern of wealth-income ratios we need to assume constant capital gains $\mathrm{q}_{\mathrm{t}}=+2.4 \%$. Given that the savings-induced wealth growth rate over this period was $g_{w s t}=+5.5 \%$, this means that savings explain 69\% of aggregate wealth accumulation between 1954 and 1970, while capital gains explain $31 \%$. In case we use personal savings (method $\mathrm{n}^{\circ} 2$ ), we find a savings share of $55 \%$, and a capital gains share of $45 \%$ (see Table A17, line 1954-1970). Retained earnings again seem to account for about a third of capital gains.

[^106]We then consider the 1925-1954 sub-period and proceed in the same manner. We start from our estimated wealth-income ratio $\beta_{\mathrm{t}}=293 \%$ for 1925 , and we compute the constant rate of capital gains $\mathrm{q}_{\mathrm{t}}$ over the 1925-1954 period which generates the observed wealthincome ratio $\beta_{\mathrm{t}}=293 \%$ for 1970, given observed growth rates and savings rates over the 1929-1954 period, wealth destructions rates observed during World War 2, and dynamic equations (A.32) and (A.33). ${ }^{123}$ We find that in order to reproduce the observed 1925-1954 pattern of wealth-income ratios we need to assume constant negative capital gains $q_{t}=-$ $1.2 \%$ during those years. We do the same for the 1913-1925 period, and we find that we need to assume constant negative capital gains $q_{t}=-5.6 \%$ during those years in order to reproduce the decline from $\beta_{\mathrm{t}}=660 \%$ in 1913 to $\beta_{\mathrm{t}}=293 \%$ in 1925 . Finally, we do the same for the 1896-1913 period, and we find that we only need to assume negligible capital gains ( $\mathrm{q}_{\mathrm{t}}=0.0 \%$ ) during those years in order to reproduce the observed pattern of $\beta_{\mathrm{t}}$ between 1896 and 1913: observed savings rates are sufficient to predict almost perfectly aggregate wealth accumulation during this period.

This estimation method delivers annual series for the wealth-income ratio $\beta_{t}$ and aggregate private wealth $W_{t}$ over the 1896-1970 period. We keep the series obtained under method $\mathrm{n}^{\circ} 1$ (private savings), i.e. col. (2) of Table A1 is equal to col. (4) of Table A17 times col. (1) of Table A1. Note that the series obtained under method $\mathrm{n}^{\circ} 2$ (personal savings) are almost identical. ${ }^{124}$

## A.5.4. Applying the equations to France 1820-1913

In order to further test the consistency of our method and of our simple wealth accumulation model, we also applied the accumulation equations to the 1820-1913 period. On Table A18 we report the results obtained with decennial averages. ${ }^{125}$ Real rates of capital gains $\mathrm{q}_{\mathrm{t}}$ reported on col. (8) of Table A18 were obtained by applying equation

[^107](A.34) above. That is, $1+q_{t}$ is again defined as a residual fraction of total private wealth growth rate that cannot be accounted for by savings, i.e. as the ratio between total private wealth growth rate $1+g_{\mathrm{wt}}$ and savings-induced wealth growth rate $1+g_{\text {wst. }}$. We find that the observed 1820-1913 pattern of wealth-income ratios $\beta_{t}$ is very well accounted for by observed savings flow, and that capital gains seem to play a negligible role during the entire 1820-1913 period. The real rate of capital gains $q_{t}$ appears to be sometime positive and sometime negative, but in any case relatively small, i.e. between $-0.4 \%$ and $+0.4 \%$ per year during each decennial period, with the single exception of the 1870 s $(-1.3 \%) .{ }^{126}$ Between 1820 and 1913, the average real growth rate of national income was $\mathrm{g}_{\mathrm{t}}=1.0 \%$, while average the real growth rate of private wealth was $g_{w t}=1.3 \%$, which can be decomposed into a savings-induced private wealth growth rate $\mathrm{g}_{\mathrm{wst}}=1.4 \%$ and a real capital gains effect $\mathrm{q}_{\mathrm{t}}=-0.1 \%$ (see Table A18). Given that we face data limitations regarding the measurement of wealth-income ratios and savings rates, it is fairly obvious that real rates of capital gains as small as $-0.1 \%$ cannot really be distinguished from zero. ${ }^{127}$ It could well be that our $19^{\text {th }}$ century savings rates are slightly over-estimated, or that the rise in the wealth-income ratio is slightly under-estimated. In any case, the important finding is that both during the $19^{\text {th }}$ century and during the $20^{\text {th }}$ century, the bulk of private wealth accumulation seems to be well accounted for by savings flows. ${ }^{128}$

## A.5.5. Two centuries of wealth accumulation

We report on Table A19 summary statistics on the sources of wealth accumulation (saving vs capital gains) in France over the entire 1820-2009 period. The main lesson is that there does not seem to be large movements in the relative price of assets in the very long run. However the decompositions by subperiod reported on Table A19 also show that over a few decades capital gains and losses matter a lot. If we examine the 1913-1949 period as a whole, the main conclusion is that most of the decline in the wealth-income ratio is due to the decline in the relative price of assets, rather than by war destructions. If we add up

[^108]war destructions estimates for World Wars 1 and 2, total destructions seem to represent the equivalent of about $30 \%$ of the 1913 capital stock. Given that the wealth-income ratio declined by about 60\% between 1913 and 1949, one might be tempted to conclude that destructions explain about half of the fall. However this is misleading, because savings were relatively high during this period, particularly in the 1920s and late 1940s, presumably as a response to the destructions (as least in part). On the basis of destructions and savings flow, private wealth should have risen at about $0.9 \%$ per year between 1913 and 1949, i.e. only slightly less than national income (1.3\%). However in fact it declined by $1.7 \%$ per year, due to a negative asset price effect ( $-2.6 \%$ ). So relatively to national income, private wealth declined at a rate of $3.0 \%$ per year, out of which only $0.4 \%$ can be attributed to volume effects (destructions and savings), i.e. about $10 \%$, and $2.6 \%$ can be attributed the decline in the relative price of assets, i.e. about $90 \%$.

Regarding the recent period, the interesting lesson from Table A19 is the following. The recovery of asset prices has played an important role in the rebound of the wealth-income ratio, but the bulk of private wealth accumulation and private wealth recovery came from saving. Between 1949 and 1979, national income grew at $5.2 \%$ per year, while private wealth grew at $6.2 \%$ per year. Out of these $6.2 \%$ per year, $5.4 \%$ can be accounted for by savings, and $0.8 \%$ are left for capital gains. Between 1979 and 2009, national income grew at $1.7 \%$ per year, while private wealth grew at $3.8 \%$ per year. Out of these $3.8 \%$ per year, $2.8 \%$ can be accounted for by savings, and $1.0 \%$ are left for capital gains.

Of course, if one looks at the detailed decennial and annual data, one can see much bigger contributions of capital gains (or capital losses). E.g. between 1999 and 2009, national income grew at $1.4 \%$ per year, while private wealth grew at $6.7 \%$ per year, out of which $2.3 \%$ can be accounted for by savings and $4.3 \%$ by capital gains. The large rise of asset prices during the 2000s is largely responsible for the booming wealth-income ratio, which was gradually rising from about $200 \%$ in the 1950 s to about $350 \%$ in the 1990s, before suddenly reaching $500 \%-550 \%$ in the 2000s. According to the latest data (January $1^{\text {st }} 2009$ ), the wealth-income ratio declined from $563 \%$ in 2008 to $552 \%$ in 2009. How far this is going to continue and whether asset prices are going to keep falling is certainly a complicated issue. The important point that we would like to stress, however, is that when we take a medium run perspective, one should not exaggerate the importance of the asset price boom of the 2000s. During each single decade of the 1949-2009 period (including the 2000s), the growth rate of national income was substantially below the savings-
induced growth rate of private wealth. The only exception was the 1960s: the savings rate was high (13.8\%), but the growth rate of national income was so high (6.2\%) that this was not sufficient to make private wealth grow faster. More generally, the savings rate was somewhat bigger during the 1949-1979 period (13.4\%) than during the 1979-2009 (9.5\%), but growth was so much smaller during the second period that the gap between income growth and savings-induced wealth growth was substantially bigger in the 1979-2009 period than in the 1949-1979 period. This is what explains - in an accounting sense - why the wealth-income ratio grew faster during the 1979-2009 period than during the 19491979 period. The capital gains effect appears to have been similar during the two subperiods ( $1.0 \%$ vs $0.8 \%$ ). If we take the $1949-2009$ period as a whole, the recovery of asset prices relatively to consumer prices appears to have been relatively steady - or at least less chaotic than one might think at first stance. The 1949-2009 increase in asset prices (at 0.8\%-1\% per year) seems to have almost fully compensated the 1913-1949 fall in asset prices (at $-2.4 \%$ per year), so that the overall capital gain effect between 1913 and 2009 appears to be fairly modest (-0.3\%).

## A.5.6. Discussion of the method and comparison with asset price indexes

How reliable is our estimation method? We feel that it is reasonably reliable, given our purposes in this research. First, as long as our raw wealth-income ratio estimates for 1201896, 1913, 1925, 1954 and 1970-2009 are reliable, the choice of what is essentially an interpolation method for missing years is not going to make an enormous difference - at least as far as decennial averages are concerned.

Next, and most importantly, we find it reinsuring - and interesting in its own right - that the wealth accumulation equation works so well in the medium and long run. In particular, the average real rates of capital gains that we need to assume in order to reproduce the pattern of wealth-income ratios over each sub-period (1820-1896, 1896-1913, 1913-1925, 1925-1954, 1954-1970) are consistent with available asset price series. Take the 19541970 sub-period. Consumer prices grew on average by 4.9\% a year during this period. But available real estate and stock market indexes show that nominal housing prices (17.4\% a year) and equity prices (7.0\%) grew substantially faster (see Table A22, line 1954-1970). So it is not surprising that we need to assume positive real rates of capital gains to account for observed wealth accumulation over this period. Conversely, during the 1913-1925 and 1925-1954 sub-periods, consumer price inflation was very large (resp. 12.4\% and 13.4\%
per year during each sub-period), and available asset price indexes show that nominal housing price inflation (resp. 5.4\% and 9.0\%) and equity price inflation (resp. 6.0\% and 10.1\%) stood at substantially lower levels (see Table A22, lines 1913-1925 and 19251954). So it is not surprising that we need to assume negative real rates of capital gains to account for observed wealth accumulation during the 1913-1954 period, and particularly so in the 1913-1925 sub-period. ${ }^{129}$ Prior to 1913, and in fact during the entire 1820-1913 period, both consumer and asset price inflation was generally low (usually less than $1 \%-$ $2 \%$ a year from a decennial average perspective), so it is not surprising that we only need to assume negligible rates of capital gains to reproduce the observed pattern of wealthincome ratios between 1896 and 1913, and more generally during the entire 1820-1913 period (see below).

Of course it is highly unsatisfactory and arbitrary to assume fixed real rates of capital gains $q_{t}$ during each sub period 1896-1913, 1913-1925, 1925-1954 and 1954-1970 (this is probably less important for the 1820-1896 period). Annual wealth accounts available for the 1970-2009 period show that real rates of capital gains can vary enormously on a year-to-year basis, and available asset price indexes show that the same conclusion certainly applies as well to the 1914-1969 chaotic period. The reason why we finally decided to use our simple method to construct our annual private wealth series, and not to use annual asset price indexes, is because is the latter appear to be of insufficient quality.

There are two conceptual and practical problems with existing historical asset price indexes (see Tables A20-A22). First, they typically cover a limited set of broad asset categories, and it is unclear how one should weight them in order to reproduce the average asset portfolio owned by private individuals at a given point in time. In France, economic historians and statisticians have constructed an index for Paris housing prices starting in 1840, an housing price index for the all of France starting in 1936, and an aggregate index for equity prices starting in $1886 .{ }^{130}$ Using these raw indexes, we attempted to construct a composite asset price index. By assuming a simple, constant

[^109]portfolio allocation, ${ }^{131}$ one can easily generate a composite index which broadly resembles our real rates of capital gains $q_{t}$ over each sub period. ${ }^{132}$ However in order to match perfectly our real rates of capital gains $\mathrm{q}_{\mathrm{t}}$, one would need to make somewhat arbitrary assumptions about changing portfolio shares.

Most importantly, we noticed that using such a composite price index in order to construct annual series for wealth-income ratios $\beta_{t}$ and aggregate private wealth $W_{t}$ would generate series with implausibly large year-to-year variations (both downwards and upwards). This seems to be due to the fact that existing asset price indexes give excessive weights on a few specific assets (real estate indexes typically rely on a limited set of housing sales in Paris and a few other cities; equity indexes exclusively rely on quoted shares), while private individuals taken as a whole own a very diversified portfolio of assets, whose short run price variations tend to offset one another, at least partly. Using such a method would also lead us to overestimate some of the medium-run, asset-prices-induced changed in aggregate private wealth. In particular, the 1913-1954 fall in real estate and equity prices (relative to CPI ) is so large in raw asset price indexes that such series are bound to lead to implausibly small wealth-income ratios $\beta_{\mathrm{t}}$ in the 1950s, even if we put very small portfolio weight on real estate and equity. ${ }^{133}$ Given that we are mostly interested in decennial averages in the context of this research on long run trends, we decided to leave this complicated issue for further work and to keep our simplifying assumptions about constant real rates of capital gains during each sub-period.

Together with the fact that they tend to overestimate short-run and medium-run variations, the other important problem with existing asset price indexes is that they seem to overestimate the long term rise of asset prices relatively to consumer prices. According to our $q_{t}$ series, which were computed as the residual term to the wealth accumulation

[^110]equation (i.e. without using asset price indexes), asset prices have risen approximately at the same pace as consumer prices over the course of the $20^{\text {th }}$ century. The real rate of capital gains $q_{t}$ was equal to $0.0 \%$ in 1896-1913, $-2.8 \%$ in 1913-1949, $+0.8 \%$ in 1949-1979 and $+1.0 \%$ in 1979-2009, so that the 1913-1949 fall and the 1949-2009 rise almost exactly compensate one another: the cumulated annualized rate of capital gains over the entire 1896-2009 period appears to be as small as $-0.3 \%$ (see Table A19, col. (5)). To put it differently: savings appear to be the primary determinant of aggregate private wealth accumulation in the long run; if anything, capital gains have played a (small) negative role over the 1896-2009 taken as a whole.

Note that if we do the same computations using method $\mathrm{n}^{\circ} 2$ (with the personal savings definition, i.e. excluding corporate retained earnings), then the small negative real rate of capital gains $q_{t}=-0.3 \%$ becomes a small positive real rate of capital gains $q_{t}=+0.4 \%$ (see Table A19, col. (9)). Taken literally, these estimates mean that assets prices are about 40\% larger in 2009 than what they were at the eve of World War 1 (relatively to consumer prices), but that if we take into account the value of accumulated retained earnings within corporations, then they are actually $30 \%$ smaller. Of course, given the data limitations, and particularly given the uncertainty about savings rates and depreciation rates, it does not make much sense to pretend that one can really distinguish between a $-0.3 \%$ and $+0.4 \%$ annualized average real rate of capital gains over a century-long period. What these findings indicate is simply that the average real rate of capital gains over the $20^{\text {th }}$ century was apparently relatively close to $0 \%$. We certainly do not infer from this finding that real capital gains will be $0 \%$ during the $21^{\text {st }}$ century. The experience of the $20^{\text {th }}$ century certainly show that major shocks can create large gaps between asset and consumer prices that last over several decades. Also, one can easily construct theoretical wealth accumulation models with two goods and long run divergence between the price of the asset good (say, real estate) and the price of consumer good. We have nothing to say as to whether such models might be relevant for the future. At a more modest level, the conclusion we draw from our computations is that the 1913-1949 drop in asset prices seems to have been more or less compensated by the 1949-2009 rise in asset prices, and that over the whole 1896-2009 aggregate wealth accumulation seems to be well accounted for by measured savings flows.

In any case, we feel that this conclusion (and the national-accounts-based computations leading to this conclusion) is more meaningful than the conclusions and computations one
can draw from existing historical asset price indexes. E.g. according to available real estate price indexes, housing prices in Paris grew 1.2\% faster than consumer prices on average over the 1896-2009 period: real housing price inflation (relatively to CPI) was $+0.6 \%$ in 1896-1913, $-6.9 \%$ in 1913-1949 and $+7.1 \%$ in 1949-2009 $+11.1 \%$ in 1949-1979, $+3.1 \%$ in 1979-2009), but on the whole the balance stood positive at $+1 . \%$ (see Table A22, col. (8)). This can look like a small number, but this is much larger than $0.3 \%-0.4 \%$ : if we cumulate $1.2 \%$ over 113 years, we obtain about 400\%, i.e. the Paris real estate price index is currently four times larger than the consumer price index (relatively to 1896-1913 levels). ${ }^{134}$ If this kind of long run asset price movement was representative of average asset prices, this would imply that wealth-income ratios $\beta_{t}=W_{t} / Y_{t}$ should have risen enormously over the $20^{\text {th }}$ century, even in the complete absence of savings. This does not make much sense.

One key reason why such computations are not really meaningful is because historical real estate indexes generally include no adjustment whatsoever for quality improvement: in effect we are comparing the price of a 1900 Paris apartment with no toilet and limted water and heating supply with the price of 2000 Paris apartment with multiple bathrooms and cable tv. Consumer price indexes do include substantial corrections for quality improvements (otherwise consumer price inflation would look much larger, and real growth in living standards would look much smaller). Assuming that quality improvements are not properly included in price indexes for capital goods such as housing (and they are arguably even more difficult to include for capital goods than for consumer goods), then it is not too surprising to find that the price of assets mechanically rises in the long run relatively to consumer prices. Long run biases regarding equity prices involve other effects generally going in the same direction. ${ }^{135}$ Generally speaking, there are good reasons to believe that existing historical asset price indexes (both real estate indexes and stock indexes) do not properly take into account quality and composition effects in the long run,

[^111]and are therefore ill suited for volume vs price decomposition analysis. We feel that it is conceptually and practically more consistent to compute implicit real rates of capital gains $\mathrm{q}_{\mathrm{t}}$ from the wealth accumulation equation, i.e. from the observed patterns of wealth-income ratios and savings flows, as measured by national accounts. ${ }^{136}$

## A.6. Supplementary series on price indexes (Tables A20-A22)

On Tables A20-A22 we report supplementary series on long run price indexes in France. We use these series at various points in this appendix, particularly in the previous section. Here we briefly describe how Tables A20-A22 were constructed.

The consumer price index (CPI) reported on col. (1) of Table A20 is the official Insee-SGF consumer price index. ${ }^{137}$ The real estate price indexes for Paris and the whole of France reported on col. (2)-(3) of Table A20 are borrowed to Friggit (2007), whose important work represents the most systematic historical data collection effort on real estate markets in France so far. ${ }^{138}$ The Friggit data base also includes historical indexes for total stock returns (dividend reinvested) and total bond returns (interest reinvested), which we report on col. (5)-(6) of Table A20. ${ }^{139}$ We also report on col. (4) a simple equity price index (no dividend reinvested) based upon series from Friggit (2007) and Villa (1994). ${ }^{140}$ All other series reported on Tables A20-A22 were computed from these raw series (and/or from previous tables).

[^112]
## Appendix B: Estate Tax Data

The other key data source used in this research is estate tax data. The main data sources and methodological issues regarding French estate tax data and the way we use it, in particular in order to compute the fiscal inheritance flow $B_{t}{ }^{f}$ and the $\mu_{t}$ ratio, are discussed in the working paper (see sections 3.1 and 3.3 ). In this appendix we provide the complete series used in this research, as well as additional details about sources, methodology and concepts.

In section B1 we describe how we computed our fiscal inheritance flow series $B_{t}{ }^{f}$. In section B2 we describe how we used estate-tax-based age-wealth profiles $\mathrm{w}_{\mathrm{t}}(\mathrm{a})$ in order to compute our $\mu_{\mathrm{t}}$ ratio series.

## B.1. Computation of the fiscal inheritance flow B $_{t}{ }^{f}$ series

Our fiscal inheritance flow series are reported on Tables B1 (annual series) and B2 (decennial averages). We start from the raw fiscal series $\mathrm{Bt}_{\mathrm{t}}^{\mathrm{f0}}$ (col.(1)), to our final corrected series $B_{t}{ }^{f}$ (col. (10)). Here we describe the data sources and methods used to make the relevant corrections and construct these tables.

Tables B1-B2, col. (1) : B $^{\text {f0 }}=$ raw fiscal bequest flow

We start from the raw bequest flow reported on estate tax returns (with no adjustment whatsoever), which we note $\mathrm{B}_{\mathrm{t}}^{\mathrm{f0}}$ (col. (1)). In the same way as in the national accounts appendix, all money values reported on Tables B1 and B2 are expressed in current billions currency, by which we mean current billions euros for the 1949-2009 period and current billions old francs for the 1820-1948 period. ${ }^{141}$

The raw bequest flow series $B_{t}^{\text {f0 }}$ reported on col.(1) come directly from the estate tax data published by the French Finance Ministry during the 1826-1964 period, and from the socalled "DMTG" micro-files of estate tax returns compiled by the French Ministry of Finance

[^113]during the 1977-2006 period. ${ }^{142}$ Throughout the period, we use a net wealth concept: the raw bequest flow $B_{t}{ }^{\text {f0 }}$ is defined as the aggregate market value of all tangible and financial assets (minus financial liabilities) transmitted at death during a given year, as reported by heirs to tax authorities. ${ }^{143}$ I.e. in 1826 a total net wealth value of 1.270 billions francs was left by decedents; in 1913 this total value was equal to 5.612 billions francs; in 2006 it was equal to 58.850 billions euros.

Between 1826 and 1964, detailed estate tax data was published quasi-annually by the French Finance Ministry. In particular, the basic annual series on aggregate bequest flows cover the entire 1826-1964 period on a continuous, annual basis (with the single exception of years 1914-1920, 1923-1924, 1961 and 1963). Complete retrospective 1826-1964 series on aggregate flows were published in the historical statistics yearbook compiled in 1966 by Insee, which constitutes our basic source for col. (1) of table B1. ${ }^{144}$ One can also find the same aggregate series in the annual tabulations reporting the number and value of estates broken down by estate bracket. The French Finance Ministry started compiling such tabulations in 1902, when the estate tax became progressive, and published them until 1964 . ${ }^{145}$

[^114]In 1964, the French administration stopped compiling and publishing annual estate tax statistics altogether. The only data available on an annual basis since 1964 are the total number of estate tax returns and the value of aggregate estate tax receipts - from which it is impossible to infer the value of the aggregate bequest flow in a reliable way, given tax progressivity. ${ }^{146}$ Fortunately, the French Finance Ministry has been collecting every 6-7 years since 1977 nationally representative samples of estate tax returns, primarily for internal tax simulation purposes. These DMTG micro files exist for years 1977, 1984, 1987, 1994, 2000 and 2006. ${ }^{147}$ Each file contains between 3,000 and 5,000 individual estate tax returns (as compared to a total of about 300,000 estate tax returns filed each year, i.e. the average sampling rate is typically slightly above $1 / 100$ ), but is heavily stratified, with a sampling rate as high as $1 / 4$ within the top percentile of decedents. Each file includes all variables reported in the estate tax return, and in particular detailed information on the value of the estates (broken down using a large number of asset categories: residential vs non-residential real estate, public vs private equity, bonds, cash, etc.), the share of total estate going to each successor, as well as basic sociodemographic information on the decedent and on each heir.

These DMTG files provide very rich information on intergenerational wealth transmission in France, and the present research relies heavily on this data source. Although these files have been compiled by the tax administration primarily for internal purposes, they have regularly been used by researchers outside the tax administration since 1984, both at Insee and outside Insee. ${ }^{148}$ The 1977 DMTG file has apparently not been archived in an accessible computer format, so we used the aggregate bequest flow estimated and published by Insee researchers who had access to this file during the 1980s. ${ }^{149}$ The 2006

[^115]DMTG file has not been made available to researchers outside the Finance Ministry yet, so we used the aggregate bequest flow recently estimated and published in an official tax administration report. ${ }^{150}$ The raw fiscal flows reported on col.(1) of Table B1 for years 1984-1987-1994-2000 come from our own computations using the corresponding DMTG micro files, and are consistent with available published estimates. ${ }^{151}$

Finally, note that we did not make any adjustment in order to correct for the time gap between time of death and time of tax filing. That is, throughout the period of study, estate tax data always refers to the calendar year when the estate tax return was filed, rather than the calendar year of death. Both calendar years do not perfectly correspond, because successors are given by law a six-month delay following the date of death in order to fill an estate tax return. E.g. the aggregate bequest flow of 58.9 billions euros reported on Table B1 for year 2006 represents the total value of bequests reported in estate tax returns filed in 2006, and includes a number of estates of individuals who died in early 2006 and a number of individuals who died in late 2005 (and in some rare cases in early 2005 or even in 2004, when successors are running late). Estate values are always estimated at the time of death (rather than at the time the return is filled and registered), this can potentially create a non-trivial downward bias in our estimated fiscal flows during periods of rapid asset price inflation. Our fiscal inheritance flows are primarily meant to be compared with economic inheritance flows based upon national wealth estimates (which are estimated on January $1^{\text {st }}$ of each year, see Appendix A), so we decided that the simplest strategy was to make no adjustment whatsoever: if successors take about six months to fill their return, then on average asset values correspond approximately to January $1^{\text {st }}$ prices. Detailed data from the DMTG files for the recent period (unlike published statistics, micro-files do include full details about date of death and date of registration) suggests however that the

[^116]six-month delay rule is not being enforced very strictly, and therefore that our simplifying assumption probably results into a slight downward bias for our fiscal inheritance flow estimates. ${ }^{152}$

## Tables B1-B2, col. (2) to (4): correction for non-filers

The first adjustment that needs to be made to the raw fiscal series has to do with nonfilers, i.e. with the fact that in a number of cases successors do not file an estate tax return. That is, we upgraded the raw fiscal series $\mathrm{B}_{\mathrm{t}}{ }^{\text {f0 }}$ (col. (1)) in order to obtain corrected estimates $\mathrm{B}_{\mathrm{t}}{ }^{\mathrm{f1}}$ (col. (3)) of the aggregate fiscal flow including non-filers. Our estimated upgrade factor $\mathrm{B}_{\mathrm{t}} / 1 / \mathrm{B}_{\mathrm{t}}{ }^{f 0}$ is reported on col. (2), and the corresponding share of non-filers in the corrected aggregate flow $\left(\mathrm{B}_{\mathrm{t}}^{\mathrm{f1}}-\mathrm{B}_{\mathrm{t}}{ }^{\mathrm{f0}}\right) / \mathrm{B}_{\mathrm{t}}^{\mathrm{f1}}$ is reported on col. (4). Col. (3) of Table B 1 was obtained by multiplying col. (1) by col. (2). Although our estimated upgrade factor $B_{t}^{f 1} / B_{t}{ }^{f 0}$ is fairly small (usually 105\%-110\% at most, except in the late 1950s-early 1960s, when it reaches $120 \%-130 \%$ ), with no long run trend, we try to be precise about where our estimates come from. Before we describe the formulas we use for the non-filers corrections, it is useful to briefly summarize how and why the fraction of non-filers decedents has evolved over time.

Until 1956, all successors were required by law to fill an estate tax return, no matter how small the estate was. In particular, there was no tax exemption threshold of any kind. Tax rates - and graduated tax schedules, following the introduction of estate tax progressivity in 1901 - did vary widely, both over time and across categories of successors, as they have always done in France (children and spouses have always faced much lower tax rates than other heirs). But the key point is that until 1956 every positive bequest was subject to a positive tax, i.e. there was no base exemption, no zero rate bracket, no matters who the heirs were. So in principle there should be no need to make any correction for non-filers prior to 1956. In practice, the number of estate tax returns filled each year fluctuated around 50\%-70\% of the annual number of decedents aged 20-yearold during the 1826-1955 period (typically, about 300,000-400,000 annual tax returns, vs

[^117]about 500,000-600,000 adult decedents per year). ${ }^{153}$ Given that the bottom $50 \%$ of the population generally holds very little wealth (always less than 10\% of aggregate wealth, and usually about $5 \%$ ), this suggests that the law was indeed applied very strictly: only successors with very small estates could escape their tax filing duties. I.e. the effective filling threshold was probably positive but extremely small. ${ }^{154}$ For the sake of consistency, however, we do compute a non-filers upgrade factor for the 1826-1955 period, using the same method as for the 1956-2006 period (see below).

In 1956, for the very first time, a tax exemption threshold was introduced into the French estate tax system. The number of estate tax returns suddenly dropped from 250,000 in 1955 to 65,000 in 1956, i.e. from $50 \%$ of the number of adult decedents to less than $15 \% .{ }^{155}$ However, the nominal exemption threshold introduced in 1956 was updated very rarely since then - and in any case much less rapidly than inflation. As a consequence the annual number of estate tax returns gradually returned to its original level: $25 \%$ of the number of adult decedents by 1964, about 50\% in the 1970s-1980s, and approximately 60\%-70\% during the 1990s-2000s (i.e. again around 300,000-350,000 annual returns, vs $500,000-550,000$ adult decedents). Note that many of these estate tax returns are currently facing no tax liability. ${ }^{156}$ E.g. during the 1990s-2000s, the number of taxable estate tax returns (i.e. with returns with positive tax liability) was only about 100,000150,000 each year, i.e. approximately $20 \%$ of the number of adult decedents. ${ }^{157}$ This is

[^118]because the filling threshold (i.e. the wealth level above which all estates need to be reported to tax authorities, whether or not heirs end up paying a positive tax) is currently much lower than the tax exemption threshold (i.e. the wealth level above which one starts paying estate taxes), which for spouses and children heirs was raised much faster than the filling threshold since 1956, particularly in the most recent period. For children heirs, following a series of increases in the 2000s (most recently in 2007), the tax filing threshold is currently 50,000 euros (in terms of total gross assets left by the decedent), while the tax exemption threshold is currently to 150,000 euros (in terms of per children bequest). ${ }^{158}$ Note that the latest rise in the tax filling threshold (2007) was not in force at the time of our latest data point (2006). The number of returns (338,000 returns in 2006, i.e. $66 \%$ of the number of decedents) probably declined somewhat in 2007 and subsequent years (no data is available yet). Of course, in case the tax filling threshold of 50,000 euros (about $25 \%$ of average per adult wealth, currently around 200,000 euros) ${ }^{159}$ is further raised importantly in the future, then the tax filers fraction of decedents might decline more significantly. In case this happens, the non-filers correction would then become a more

[^119]serious issue, and French estate tax data would loose some of its exceptional quality in comparison to other countries. ${ }^{160}$

To summarize: except during a brief period in the late 1950s-early 1960s, the fraction of tax filers has generally been about $50 \%-60 \%$ of the annual number of adult decedents throughout the 1820-2006 period.

In order to compute the non-filers correction factor we proceed as follows. We note $\mathrm{N}_{\mathrm{dt}}{ }^{\mathrm{f}}$ the number of estate tax returns, $\mathrm{N}_{\mathrm{dt}}{ }^{20+}$ the total number of adult decedents, $\mathrm{n}_{\mathrm{dt}}{ }^{\mathrm{f}}=\mathrm{N}_{\mathrm{dt}}{ }^{\mathrm{f}} / \mathrm{N}_{\mathrm{dt}}{ }^{20+}$ the fraction of tax-filers decedents, and $\mathrm{w}_{\mathrm{dt}}{ }^{\mathrm{f}}=\mathrm{B}_{\mathrm{t}}{ }^{\mathrm{f}} / \mathrm{N}_{\mathrm{dt}}{ }^{\mathrm{f}}$ the average wealth reported by tax filers. All we need to estimate is the average wealth of non-filers $W_{d t}{ }^{n f}$. We note $z_{\mathrm{dt}}{ }^{\text {nf }}=$ $W_{d t}{ }^{\mathrm{nf}} / \mathrm{w}_{\mathrm{dt}}{ }^{\mathrm{f}}$ the ratio between non-filers and filers average wealth. Once we know $Z_{\mathrm{dt}}{ }^{\text {nf }}$, we can simply compute the non-filers correction factor by applying the following equation:

$$
\begin{align*}
& B_{t}^{f 1}=N_{d t}{ }^{f} W_{d t}{ }^{f}+\left(N_{d t}^{20+}-N_{d t}{ }^{f}\right) W_{d t}{ }^{\text {nf }}=B_{t}{ }^{f 0}\left[1+\left(1-n_{d t}{ }^{f}\right) Z_{d t}{ }^{\text {nf }}\right] \\
& \text { I.e.: } \quad B_{t}^{f 1} / B_{t}^{f 0}=1+\left(1-n_{d t}^{f}\right) z_{d t}^{n f} \tag{B.1}
\end{align*}
$$

As a first approximation, one could think of the non-filers as decedents with wealth below some effective filling threshold $w_{d t}{ }^{*}$, with $1-F_{t}\left(w_{d t}{ }^{*}\right)=n_{d t}{ }^{f}$, where $F_{t}(w)$ is the cumulative distribution function for wealth-at-death (i.e. $\mathrm{F}_{\mathrm{t}}(\mathrm{w})$ is the fraction of decedents with wealth-at-death less than w , and $1-\mathrm{F}_{\mathrm{t}}(\mathrm{w})$ is the fraction with wealth above w ). Ideally, it would certainly be interesting to model explicitly the functional form of the wealth distribution $F_{t}(w)$ and its endogenous dynamics, and then from there to derive explicit estimates for the wealth ratio $z_{\mathrm{dt}}{ }^{\text {nf }}$ between the bottom and upper parts of the distribution. However such an explicit modelling of distributions would fall far beyond the scope of the present research, where we concentrate primarily upon aggregate ratios and their evolution. Also we know that the effective filing threshold $\mathrm{w}_{\mathrm{dt}}{ }^{*}$ has always been relatively small, but we do not know its exact value: in the 1826-1955 period, it was officially supposed to be equal to zero, but in practice it was probably slightly positive; in the 1956-2006 period, it was officially slightly positive, but varied with the family structure (in particular the existence of children heirs),

[^120]so the observed wealth distribution is actually truncated downwards at slightly different levels for different sub-populations.

So instead we make the following simple approximate assumptions about the wealth ratio $Z_{\mathrm{dt}}{ }^{\text {nf }}$ (which in any case is bound to be very small). For the recent decades, we have several data sources to estimate the average wealth of non-filers. First, the wealth surveys carried out by Insee in the 1990s-2000s (similar to the U.S. Survey of consumer finances) consistently show that the bottom half of the population owns at most $5 \%-10 \%$ of aggregate wealth (this is true at all ages). ${ }^{161}$ In the U.S., the bottom $50 \%$ wealth share, as estimated in the SCF surveys of the 1990s-2000s, is even less than $5 \%{ }^{162}$ By definition, note that a $5 \%$ aggregate wealth share for the bottom $50 \%$ means that the bottom half average wealth $w_{d t}{ }^{b}$ is equal to $10 \%$ of aggregate average wealth $w_{d t}$, and to about $5.3 \%$ of the upper half average wealth $w_{d t}{ }^{u} .{ }^{163}$ I.e. this corresponds to a bottom-top wealth ratio $z_{d t}{ }^{b}$ $=W_{d t}{ }^{b} / w_{d t}^{u}=5.3 \%$. Similarly, a $10 \%$ aggregate wealth share for the bottom $50 \%$ means that $w_{d t}{ }^{\text {b }}$ is equal to $20 \%$ of aggregate average wealth $w_{d t}$, and that the bottom-top wealth ratio $z_{d t}{ }^{b}=w_{d t}{ }^{b} / w_{d t}{ }^{4}$ is about $11.1 \% .{ }^{164}$ So on the basis of wealth surveys, and considering that the non-filers approximately correspond to the bottom half of the wealth distribution, one might be tempting to assume values of about $5 \%-10 \%$ for the $z_{d t}{ }^{\text {nf }}$ ratio. However $a$ special survey conducted by the tax administration in 1988 in order to estimate the wealth of non-filers suggests that the true ratio is somewhat higher, with $z_{\mathrm{dt}}{ }^{\text {nf }}$ around $15 \%$. ${ }^{165}$ This

[^121]seems to due to the fact that in the recent decades the effective filling threshold has been substantially higher for a sub-fraction of decedents (particularly those with children), thereby raising somewhat the non-filers average wealth.

So for the 1977-2006 sub-period we assume $z_{d t}{ }^{n f}=15 \%$. For the 1826-1955 period, given that filling obligations were the same for all decedents and were applied very strictly, and given that the bottom $50 \%$ wealth share was probably at most $5 \%$ during this period (at that time top wealth shares were even larger than they are today), ${ }^{166}$ we assume $z_{\mathrm{dt}}{ }^{\mathrm{nf}}=$ 5\%. For the 1956-1964 period, on the basis of the Finance Ministry tabulations by estate size, we also find that the best approximation is $z_{d t}{ }^{\text {nf }}=5 \% .{ }^{167}$

The non-filers upgrade factor $B_{t}^{f 1} / B_{t}^{f 0}$ was therefore computed by applying equation (B.1) and by assuming $z_{d t}{ }^{\text {nf }}=5 \%$ for 1826-1964 and $z_{d t}{ }^{\text {nf }}=15 \%$ for 1977-2006. We find an upgrade factor $\mathrm{B}_{\mathrm{t}}^{\mathrm{f1}} / \mathrm{B}_{\mathrm{t}}^{\mathrm{f0}}$ around $103 \%-105 \%$ throughout the $1826-1955$ period; ${ }^{168}$ the upgrade factor then jumps to over 130\% in 1956-1957, but quickly diminishes towards $115 \%-120 \%$ in the late 1950 s-early 1960 s, and then stabilizes around $110 \%-115 \%$ in the period going from the 1970s to 2000s (see Table B1, col. (2)). We tried several alternative assumptions, and we found that the impact on upgrade factors was relatively small (less than 5\%).

## Tables B1-B2, col. (5) to (7): correction for tax-exempt assets

The second adjustment that needs to be made to the raw fiscal series has to do with taxexempt assets, i.e. with the fact that a number of assets are legally exempt from estate taxation and are generally not reported on estate tax returns. That is, we upgraded the

[^122]non-filers-corrected fiscal series $\mathrm{B}_{\mathrm{t}}{ }^{f 1}$ (col. (3)) in order to obtain corrected estimates $\mathrm{B}_{\mathrm{t}}^{\mathrm{f} 2}$ (col. (6)) of the aggregate fiscal flow including non-filers and tax-exempt assets. Our estimated upgrade factor $B_{t}^{f 2} / B_{t}^{f 1}$ is reported on col. (5), and the corresponding share of tax exempt assets in the corrected aggregate flow $\left(\mathrm{B}_{\mathrm{t}}^{\mathrm{f} 2}-\mathrm{B}_{\mathrm{t}}^{\mathrm{f1}}\right) / \mathrm{B}_{\mathrm{t}}^{\mathrm{f} 2}$ is reported on col. (7). Col. (6) was obtained by multiplying col. (3) by col. (5).

In order to estimate the fraction of tax exempt assets in the corrected aggregate flow, we proceed as follows. For the 1970-2009 period, we have detailed annual series on aggregate private wealth broken by asset categories coming from Insee-Banque de France balance sheets (see Appendix A, Table A15b). On the basis of estate tax law, and by comparing the asset composition of aggregate private wealth and the asset composition of the fiscal estate flow (as measured by 1977-2006 DMTG files), ${ }^{169}$ we make the following assumptions about the taxable and tax-exempt fractions of each asset category. ${ }^{170}$ We assume that $80 \%$ of the value of housing assets (residential real estate), as estimated by Insee-Banque de France balance sheets, was subject to the estate tax, and that $20 \%$ was tax exempt. ${ }^{171}$ For non-housing tangible assets (which include unincorporated business assets), we assume a taxable fraction of $70 \%$ and a tax exempt fraction of $30 \%{ }^{172}$ For financial assets other than private equity and life insurance (i.e. for

[^123]public equity, mutual funds, bonds, checking and savings accounts, etc.), we assume a taxable fraction of $90 \%$ and a tax exempt fraction of $10 \% .{ }^{173}$ For private equity financial assets, we assume a taxable fraction of $50 \%$ and a tax-exempt fraction of $50 \% .{ }^{174}$ Finally, for life insurance financial assets (the major tax exempt asset), we assume a taxable fraction of $5 \%$ and a tax-exempt fraction of $95 \%$. ${ }^{175}$ We then weighted these tax exempt fractions by the relative importance of each asset category in aggregate private wealth in order to estimate the overall fraction of tax-exempt assets in total wealth, which according to these computations gradually rose from about $24 \%-25 \%$ in the 1970s to about $33 \%$ $34 \%$ in the 2000s (see Table B1, col. (7)). ${ }^{176}$ This is mostly due to the rise of life insurance.

These estimates are approximate - and if anything are probably conservative, especially for the more recent period. In particular, we implicitly assume that average asset composition is the same for decedents and for aggregate private wealth. ${ }^{177}$ Insee wealth surveys suggest that the elderly actually own a larger fraction of their wealth in tax exempt assets such as life insurance, so that we probably underestimate our upgrade factor. ${ }^{178}$ Also, note that the top estate tax rate for children heirs was raised from $20 \%$ to $40 \%$ in

Note also that a number of non-housing, non-business tangible assets have long benefited from special exemption regimes in France, e.g. a number of specific rural assets like forests (see Rapport du Conseil des Impôts, 1986, p.44).
${ }^{173}$ In principle, all non-private-equity, non-life-insurance financial assets are subject to estate taxation, on the basis of their full market value. In particular, the general exemption for public bonds was suppressed in 1850, and never re-introduced. However, a number of special exemption schemes were introduced by various governments for specific assets, especially for specific public bonds issued at a given point time (many governments used this as a debt policy tool during and in the aftermath of both world wars, and the habit continued afterwards: e.g. the "emprunt Pnay" issued in the 1950s was wholly exempted from estate taxation, and so was the "emprunt Balladur" in the 1990s). In order to take this into account, we assume that $90 \%$ of the overall market value of non-equity, non-life-insurance financial assets (as measured by InseeBanque de France balance sheets) is subject to tax, and that $10 \%$ is tax exempt. This is of course approximate and ought to be refined.
${ }_{114}$ See above.
${ }^{175}$ Between 1930 and 1990, life insurance assets were entirely tax free (i.e. $100 \%$ exemption rate). Since 1991, the fraction of life insurance premiums paid after age 70 and above $30,500 €$ is subject to estate tax (not the corresponding interest). In order to take this into account we assume that a $5 \%$ fraction of life insurance assets is taxable (according to DMTG files for 1994-2000, which include virtually no life insurance assets, this is probably even lower than $5 \%$ ). Also note that a special $20 \%$ tax on the fraction of life insurance payments to successors above $152,500 €$ was instituted in 1998 . However this special tax is administered completely separately from the general estate tax, and the corresponding asset values are not reported on estate tax returns.
${ }_{177}$ See formulas in excel file.
${ }^{177}$ We attempted to compute the tax exempt fractions for various assets so as to match the observed composition of taxable estates, so in principle we correct for such biases. However the asset categories used in Insee-Banque de France balance sheets and in DMTG estate tax returns files are not exactly the same, so such computations are bound to be approximate. Also, there are virtually no life insurance assets in estate tax returns, so the age bias correction does not work for this asset.
${ }^{178}$ It is also possible that the annuitized (non-bequeathable) fraction of life-insurance assets rises with age (an issue on which we know very little), in which case the bias would go in the other direction. Given however that the overall annuitized fraction of life insurance assets is relatively small in France (see Appendix A.5), it seems unlikely that this second effect dominates.

1984: ${ }^{179}$ this possibly raised incentives for straight tax evasion, which by choice we do not attempt to include in our legal tax exemption upgrade factor. ${ }^{180}$

For the pre-1970 period we proceed as follows. We use the detailed decomposition by asset categories (including estimated tax exempt assets) regularly published by the Finance Ministry during the 1898-1964 period. These estimates show that tax-exempt assets were relatively small in 1898-1899 (about $5 \%$ of total assets, taxable and taxexempt), then fastly rose to about 15\%-20\% following the 1901 estate tax reform (the introduction of tax progressivity was accompanied by the development of legal exemptions, and according to some observers of the time by the rise of tax evasion, which we do not take into account), then stabilized at about $20 \%$ during the interwar period, and finally rose somewhat during the 1950s and early 1960s. ${ }^{181}$ Since these numbers are consistent with our independent 1970-2009 estimates, we simply link them up by assuming that the aggregate fraction of tax exempt assets rose gradually rose from $20 \%$ in 1950 to $25 \%$ in $1970 .{ }^{182}$ For the $1826-1897$ period we have very limited data to compute the fraction of tax exempt assets. However we know from estate tax law that the major exemption during the $19^{\text {th }}$ century was public debt: government bonds were entirely exempted from estate tax until 1850, while bonds issued after 1850 were all subject to tax.

[^124]Based on approximate estimates on the total value and maturity structure of government bonds, ${ }^{183}$ we assumed that the aggregate fraction of tax exempt assets rose gradually from $15 \%$ in 1826 to $20 \%$ in 1840 , stabilized at $20 \%$ between 1840 and 1855 , and then declined gradually from $20 \%$ in 1855 to $5 \%$ in 1880 , before stabilizing at $5 \%$ until $1900 .{ }^{184}$

Tables B1-B2, col. (8) to (12): correction for inter vivos gifts

The third and last adjustment that needs to be made to the raw fiscal series has to do with inter vivos gifts, i.e. with the fact that a number of assets are transmitted before death and are therefore not included in the bequest flow strictly speaking. As was explained in the working paper (section 3.1), the simplest way to take gifts into account is to add the gift flow of a given year to the bequest flow of the same year. ${ }^{185}$ This is what we do on Table B1. That is, we report on col. (8) the raw fiscal gift flow $V_{t}{ }^{f 0}$, the total net wealth value transmitted via inter vivos gifts during year $t$, as reported to tax authorities. We then compute the raw gift-bequest ratio $\mathrm{v}_{\mathrm{t}}=\mathrm{V}_{\mathrm{t}}^{\mathrm{f0}} / \mathrm{B}_{\mathrm{t}}^{\text {fo }}$ by dividing col.(8) by col.(1). We find the giftbequest ratio was relatively stable around $30 \%-40 \%$ from the 1820s to the 1850 s, then declined somewhat and stabilized around $20 \%-30 \%$ from the 1870 s to the 1970 s, and then gradually rose to about $40 \%$ in the 1980s, $60 \%-70 \%$ in the 1990s and over $80 \%$ in the 2000s (see Table B1, col.(9)). We compute the corresponding upgrade factor $1+\mathrm{v}_{\mathrm{t}}$ (col. (11)), which we multiply by non-filers-and-tax-exempt-assets-corrected fiscal series $B_{t}^{f 2}$ (col. (6)) in order to obtain our final estimates $\mathrm{B}_{\mathrm{t}}^{\mathrm{f} 2}$ of the fiscal inheritance flow (col.(10)). In effect, we are assuming that the same upward correction for non-filers and tax-exempt assets apply to bequests and gifts, which as a first approximation seems like the most natural assumption (though it probably understates the true economic importance of gifts). ${ }^{186}$

[^125]Our raw fiscal gift flow series (col.(8)) comes from the same data sources as the raw fiscal bequest flow, i.e. published Finance Ministry aggregate annual series for the 1826-1964 period, ${ }^{187}$ and DMTG micro files estimates for the 1977-1984-1987-1994-2000-2006 period. ${ }^{188}$ Given the importance of the gift-bequest ratio parameter $v_{t}$, it would obviously be preferable to have annual series on the gift and bequest flows for the entire period. ${ }^{189}$ However we feel reinsured by the fact that the data points at our disposal do show a relatively regular and gradual evolution of the gift-bequest ratio in the long run, including during the recent decades. ${ }^{190}$

Note that inter vivos gifts have always benefited from a number of tax advantages in the French system of bequest and gift taxation. Prior to 1901, there was no explicit tax advantage for gifts: bequests and gifts were subject to similarly low proportional tax rates (varying only with the identity of the heir or donee). The main tax advantage was due to capital gains (and capitalized interest): by giving an asset earlier in life one pays lower taxes, simply because its value is generally lower than at the time of death. With the

[^126]introduction of tax progressivity in 1901, another implicit tax incentive was created: by splitting an estate into several pieces one could end up in lower tax brackets and hence pay lower total taxes. ${ }^{191}$ With the rise of top tax rates in the interwar period, this became increasingly problematic, and in 1942 a major reform was enacted in order to unify the bequest and gift taxes. Since 1942 until the present day, the general rule is that the same graduated tax schedules apply to both bequests and gifts, and most importantly that all inter vivos gifts are "recalled" when the donor dies and are added to the bequest left at death, so that each heir ends up paying taxes on the basis of the total estate he or she received from the decedent. In principle, the system is designed so as to achieve full tax neutrality between gifts and bequests: if you want to transfer a given asset to your kid, then the total tax burden is the same whether you transmit half now and half at your death or you transmit it entirely at your death. ${ }^{192}$

In practice, however, gifts remained less taxed than bequests after 1942, and these tax advantages were significantly reinforced in the late 1990s and in the 2000s. First, the 1942 reform did not eliminate the capital gains (and capitalized interest) tax advantage: recalled gifts have always been valued at the time they were made, not at the time of death. In times of high inflation and even more rapidly rising asset values, this can make a big difference. ${ }^{193}$ Next, the 1942 reform created a special $25 \%$ tax rebate for so called "sharing gifts" ("donations-partages"), i.e. inter vivos gifts with equal sharing between all children. This special $25 \%$ tax rebate regime was abolished in 1981, but then re-introduced in 1986 for "sharing gifts" made by donors aged less than 65-year-old (no such age condition existed in the 1942-1981 regime). This was then extended in 1996-1998 to all gifts made

[^127]by donors aged less than 65 -year-old; it is still in place today. ${ }^{194}$ In effect, this special regime became a policy tool to favour early estate transmission to children, together with other temporary regimes enacted in the late 1990s and the 2000s. ${ }^{195}$ Finally, the so-called "10 year rule" was introduced in 1992, which significantly altered the general principle of "recalled gifts" instituted in 1942. Since 1992, gifts made more than 10 years before the time of death are not recalled any more. I.e. they still pay gift tax at the time they are made, but they are not added any more to the estate when the bequest tax is computed. In 2006, the "10 year rule" became a " 6 year rule". ${ }^{196}$

It is plausible that the increased tax advantages given to gifts in the 1990s-2000s did contribute to the recent rise of the gift-bequest ratio $v_{t}$. Because we do not have annual data, it is difficult however to isolate the impact of tax incentives per se, as opposed to the many non-tax-related reasons that could explain the rise in $\mathrm{v}_{\mathrm{t}}$. In particular, it is equally plausible that rising age expectancy alone can explain why parents start giving away larger fractions of their wealth in inter vivos gifts (e.g. so as to help their children to buy a home at a reasonably early age), quite independently from tax incentives. Given that the rise of the gift-bequest ratio $\mathrm{v}_{\mathrm{t}}$ appears to start in the 1980s and early 1990s, i.e. before the

[^128]changes in tax incentives, one is tempted to conclude that non-tax factors played a dominant role. Also note that parents did not start making gifts earlier in life in recent decades: the average age gap between decedents and donors appears to have been relatively stable around 7-8 years since the 1960s, and in particular during the 1980s-1990s-2000s. ${ }^{197}$ This suggests that the new tax incentives (most of which decline with age) did not play a major role, or at least did not have the impact expected by policy makers. In any case, note that whether tax factors or non-tax factors explain the observed rise of the gift-bequest ratio $\mathrm{v}_{\mathrm{t}}$ since the 1970s, and in particular the very high levels observed in the 2000s (over $80 \%$ ), is not really relevant for our purposes in this research. What is potentially more relevant is to know whether there has been some kind of "overshooting" of gifts in the recent past in France, in the sense that the relatively large bequests-plus-gifts flows observed in the 2000s might not be sustainable (i.e. because the cohorts who made unusually large gifts in the 2000s will also leave unusually small bequests in the 2010s). We address this issue when we present the results from the simulated model (see Appendix D).

## B.2. Data on the age profile of wealth $w_{t}(a)$ and computation of the $\mu_{t}$ ratio

Our series on age-wealth profiles $\mathrm{w}_{\mathrm{t}}(\mathrm{a})$ and our resulting estimates of $\mu_{\mathrm{t}}$ ratios are reported on Tables B3 to B5. Here we describe the data sources and methods used to construct these tables.

Table B3: Raw data on the age-wealth profile of decedents $\mathrm{w}_{\mathrm{dt}}(\mathrm{a}), 1820-2006$

On Table B3 we report our raw data on the age-wealth profiles of decedents. We note $\mathrm{w}_{\mathrm{dt}}(\mathrm{a})$ the average wealth at death of decedents of age a (i.e. the average estate left by decedents of age $a),{ }^{198}$ and $w_{t}(a)$ the average wealth of living individuals of age a. In case decedents of each age group are a representative sample of the living, i.e. under the uniform mortality assumption, then by definition $w_{d t}(a)=w_{t}(a)$. However, in practice, there exists extensive empirical evidence showing that differential mortality between the rich and the poor is quantitatively important and age-varying, i.e. $w_{d t}(a)$ is smaller than $w_{t}(a)$ and the gap varies with age. So it is critical to correct our raw wealth-at-death age profiles $\mathrm{w}_{\mathrm{dt}}(\mathrm{a})$

[^129](Table B3) in order to compute corrected wealth-of-the-living age profiles $\mathrm{w}_{\mathrm{t}}(\mathrm{a})$ (Table B4), before we can properly compute the $\mu_{\mathrm{t}}$ ratio (Table B5). For now we present the raw wealth-at-death age profiles $\mathrm{w}_{\mathrm{dt}}(\mathrm{a})$ reported on Table B3.

Our raw data on the age profile of wealth-at-death $\mathrm{w}_{\mathrm{dt}}(\mathrm{a})$ comes from published estate tax tabulations and from estate tax micro-files (see below). Given that we are solely interested in the relative age profile of wealth (and not in the absolute wealth levels per se), and in order to ensure easy comparability of the profiles over time, we choose to express our data on age-wealth profiles in terms of $\mathrm{w}_{\mathrm{dt}}(\mathrm{a}) / \mathrm{w}_{\mathrm{dt}}{ }^{50-59}$ ratios, i.e. we express the average wealth of all age groups as a fraction of average wealth of decedents aged 50-to-59-yearold. E.g. in 2006 the average wealth of decedents aged 80-year-old and over was equal to $134 \%$ of the average wealth of decedents aged 50 -to- 59 -year-old, the average wealth of decedents aged 70 -to-79-year-old was equal to $106 \%$ of the average wealth of decedents aged 50-to-59-year-old, etc.

Our raw data suffers from a number of limitations. First, because published estate tax tabulations used age brackets $0-9,10-19,20-29, \ldots, 70-79,80$ and over, and also because of the limited sample size of DMTG micro-files, we also used these decennial age brackets to estimate $\mu_{\mathrm{t}}$ ratios, i.e. we did not attempt to estimate the shape of continuous $\mathrm{w}_{\mathrm{dt}}(\mathrm{a})$ agewealth profiles.

Next, age-wealth profiles are available only for a limited number of years. For the 19772006 period, we used the age-wealth profiles coming from the DMTG micro files. Unfortunately the age data from the initial DMTG 1977 file is not usable, ${ }^{199}$ so for the post1977 period we only report on Table B3 raw age-wealth profiles for years 1984, 1987, 1994, 2000 and $2006 .{ }^{200}$

[^130]For the 1902-1964 period, we can use the Finance Ministry tabulations broken down by age bracket. Similarly to the tables indicating the number and value of estates broken down by estate bracket, the Finance Ministry tables indicating the number and value of estates broken down by age bracket rely on the exhaustive set of all estate tax returns during a given year, so the resulting age-wealth profiles are extremely reliable. Unfortunately, while the estate-bracket tables were compiled and published by the French tax administration on a quasi-annual basis during the entire 1902-1964 period, the agebracket tables were established solely during the 1943-1964 period. ${ }^{201}$ Prior to 1943, age tables were compiled and published in 1906, 1908, 1928 and 1934, but they solely report the number (and not the value) of estates broken down by age bracket. ${ }^{202}$ So for the pre1943 period, the age-wealth profiles reported on Table B3 rely primarily the exhaustive micro files of all individual estate tax returns filed in Paris in 1807, 1812, 1817, etc., 1937 compiled every 5 years by Piketty, Postel-Vinay and Rosenthal (2006). This is certainly a very rich data base (we know full individual-level details about assets, decedents and heirs), and Paris alone was a pretty big part of France wealth-wise during the $19^{\text {th }}$ century and the first half of the $20^{\text {th }}$ century. ${ }^{203}$ However there is no reason to believe that Paris age-wealth profile are representative of the whole of France, so we used several other sources in order to carefully convert our observed Paris profiles into the national profile estimates reported on Table B1 for the pre-1943 period.

First, thanks to the Finance Ministry 1943-1964 tabulations and to the DMTG 1977-2006 micro files, we do observe separately Paris and France-minus-Paris age-wealth profiles for the whole post-1943 period. ${ }^{204}$ We find that the Paris profile has always been more strongly upward sloping than the national profile (relatively to the 50-to-59-year-old, the 60-to-69, 70-to-79 and 80-and-over-year-old groups have always been richer in Paris than in the rest of France), but that the gap is relatively constant over time, so that one can relatively easily estimate the national profile from the Paris profile and from the Paris share

[^131]in the national bequest flow, which we know from our Paris 1807-1937 micro files. In order to test the accuracy of this method, we used the Finance Ministry 1906-1908-1928-1934 national age tables, as well as the detailed cross tabulations by estate and age brackets (with numbers and values of estates) compiled for Paris and for the Manche department (relatively representative of rural France, according to later years) compiled in a special survey organized by the tax administration in $1931 .{ }^{205}$ These tests show that our ParisFrance extrapolation method is consistent. So we feel that the estimated national agewealth profiles $\mathrm{w}_{\mathrm{dt}}(\mathrm{a})$ reported on Table B 1 for the period going from the 1890s to the 1930s are as reliable as the post-1943 profiles. ${ }^{206}$ For the earlier parts of the $19^{\text {th }}$ century, there exists no Finance Ministry national age table, and one must be careful about the fact the relative importance and wealth structure of Paris vis-à-vis the rest of France changed extensively between the 1820s and the 1890s. We used the same data sources as those used by Piketty et al (2006) in order to convert Paris wealth concentration estimates into national wealth concentration estimates. ${ }^{207}$ The resulting national age-wealth profiles reported on Table B3 for the 1820s to 1880s are certainly less precise than for the 18902006 period, and they ought to be improved. However we tried several alternative assumptions and found that these had little consequence for the $19^{\text {th }}$ century levels and patterns of the $\mu_{\mathrm{t}}$ ratio (the key parameter of interest in the context of this research), which appear to be reliable. ${ }^{208}$

[^132]Finally, note that another limitation of our raw age-wealth data throughout the 1820-2006 period is that by construction we only observe the wealth of estate tax filers. Since the proportion of decedents filling a tax return (whose heirs filled a tax return) varies with age (generally it rises with age, especially among the younger age groups), it is critical to correct for this, otherwise the age-wealth profiles could be severely biased. ${ }^{209}$ We proceed as follows. In our raw estate tax data - both in the Finance Ministry 1943-1964 tabulations and in the 1807-1937 Paris micro-files and 1977-2006 DMTG micro-files - we observe the number of estate tax returns $\mathrm{N}_{\mathrm{dt}}{ }^{\dagger}(a)$ filled for decedents of age group $a$, as well as the corresponding total estate value $\mathrm{W}_{\mathrm{dt}}{ }^{\mathrm{f}}(\mathrm{a})$ and average reported estate $\mathrm{W}_{\mathrm{dt}}{ }^{\dagger}(\mathrm{a})=$ $\mathrm{W}_{\mathrm{dt}}{ }^{\mathrm{f}}(\mathrm{a}) / \mathrm{N}_{\mathrm{dt}}{ }^{\mathrm{f}}(\mathrm{a})$. We also know from basic demographic data (see Appendix C ) the total number of decedents of age group a $\mathrm{N}_{\mathrm{dt}}(\mathrm{a})$, from which we know the number of non-filers $N_{d t}{ }^{n f}(a)=N_{d t}(a)-N_{d t}^{f}(a)$, and the proportion of filers $n_{d t}{ }^{f}(a)=N_{d t}{ }^{f}(a) / N_{d t}(a)$. What we do not directly observe is the average wealth of non-filers $W_{d t}{ }^{f}(a)$. In the same way as for the computation of the non-filers correction to the aggregate fiscal bequest flow (see section B. 1 above), we make simple assumptions about the value of the wealth ratio $\mathrm{z}_{\mathrm{dt}}{ }^{\mathrm{nf}}=$ $w_{d t}{ }^{n f}(a) / w_{d t}{ }^{f}(a)$. I.e. we assume that $z_{d t}{ }^{\text {nf }}=5 \%$ for years $1820-1964$ and $z_{d t}{ }^{n f}=15 \%$ for years 1977-2006. We then compute average wealth $\mathrm{w}_{\mathrm{dt}}(\mathrm{a})$ of all age-a decedents (filers and nonfilers) by applying the following equation:

$$
\begin{equation*}
w_{d t}(a)=\left[n_{d t}{ }^{f}(a)+\left(1-n_{d t}^{f}(a)\right) z_{d t}^{n f}\right] w_{d t}^{f}(a) \tag{B.2}
\end{equation*}
$$

It is apparent from equation (B.2) that the exact value of $z_{\mathrm{dt}}{ }^{\text {nf }}$ has a limited impact on the overall age-wealth profile $w_{d t}(a)$, and even less on the resulting $\mu_{t}$ ratio. ${ }^{210}$ The dominant effect comes from the filers fraction $n_{d t}{ }^{f}(a)$. Typically, when the aggregate fraction $n_{d t}{ }^{\mathrm{f} 20+}$ of tax filers among adult decedents is about 50\%, the observed age-level fraction of tax filers $\mathrm{n}_{\mathrm{dt}}{ }^{\dagger}(\mathrm{a})$ can be as large as $60 \%-70 \%$ for the older groups (60-69, $70-79$ and 80 -and-over), and as low as $30 \%-40$ for the younger groups (20-29, 30-39 and 40-49). The pattern varies over time, and generally tends to reinforce the effects of the average reported

[^133]wealth pattern..$^{211}$ Note that for very young decedents (0-9 and 10-19), the fraction of tax filers is very small (less than 5\% in the postwar period, and generally less than 10\% in the earlier periods): it is quite rare that children die, and it is even rarer that they die after having already inherited an estate at such an early age; so most of the time for children decedents there is no estate to report to the tax administration. As a consequence, the average wealth estimates for children decedents rely on a limited number of observations and should be viewed as approximate (they are very small anyway). ${ }^{212}$

Table B4: Corrected age-wealth profile $\mathrm{w}_{t}(\mathrm{a}), 1820-2006$

On Table B4 we report our corrected age-wealth-of-the-living profiles $\mathrm{w}_{\mathrm{t}}(\mathrm{a})$. These were obtained from the raw age-wealth-at-death profiles $\mathrm{w}_{\mathrm{dt}}(a)$ reported on Table B3, by applying the differential mortality parameters indicated on Table B4. ${ }^{213}$

On the basis of available empirical evidence (see below), we model differential mortality as follows. For each age group a, we assume that the poor (defined as the bottom half of the wealth distribution for this age group) have a higher mortality rate than the rich (defined as the upper half of the wealth distribution for this age group). That is, we note $m_{t}{ }^{P}(a)$ the mortality rate of the poor, $m_{t}^{R}(a)$ the mortality rate of the rich, and $\delta_{t}(a)=m_{t}^{P}(a) / m_{t}^{R}(a)>1$ the differential mortality ratio. By construction, $\left(m_{t}^{P}(a)+m_{t}^{R}(a)\right) / 2=m_{t}(a)$, where $m_{t}(a)=N_{d t}(a) / N_{t}(a)$ is the mortality rate of age group a during year $t, N_{d t}(a)$ is the number of decedents of age $a$, and $N_{t}(a)$ is the number of living individuals of age a. So we have:

$$
\begin{array}{ll}
m_{t}^{P}(a) / m_{t}(a)=2 \delta_{t}(a) /\left(1+\delta_{t}(a)\right) & (>1) \\
m_{t}^{R}(a) / m_{t}(a)=2 /\left(1+\delta_{t}(a)\right) & (<1) \tag{B.4}
\end{array}
$$

[^134]We also note $\operatorname{sh}_{t}{ }^{\mathrm{P}}(\mathrm{a})$ the poor's share in total wealth of age group a at time t . By construction, the average wealth of the poor $w_{t}^{P}(a)$ is equal to $2 \operatorname{sh}_{t}{ }^{P}(a) w_{t}(a)$, and the average wealth of the rich $w_{t}^{R}(a)$ is equal to $2\left(1-s h_{t}^{P}(a)\right) w_{t}(a)$. For a given age group the ratio $w_{d t}(a) / w_{t}(a)$ between the average wealth of decedents and average wealth of the living can then be computed as follows:

$$
w_{d t}(a) / w_{t}(a)=\left[2 s h_{t}^{P}(a) m_{t}^{P}(a)+2\left(1-s_{t}^{P}(a)\right) m_{t}^{R}(a)\right] /\left[m_{t}^{P}(a)+m_{t}^{R}(a)\right]
$$

I.e.:

$$
\begin{equation*}
w_{d t}(a) / w_{t}(a)=m_{t}^{P}(a) / m_{t}(a) \operatorname{sh}_{t}^{P}(a)+m_{t}^{R}(a) / m_{t}(a)\left(1-\operatorname{sh}_{t}^{P}(a)\right) \tag{B.5}
\end{equation*}
$$

Our preferred differential mortality parameters are reported on the upper part of Table B4. That is, we assume that throughout the period of study the differential mortality ratio $\delta_{t}(a)$ is equal to $200 \%$ for age groups 0-9 to 40-49 year-old, and then declines to $180 \%$ for $50-$ 59 year-old group, 150\% for 60-69 year-old group, 130\% for 70-79 year-old and 110\% for 80 -year-old and over. I.e. the mortality rate of the poor is twice as large as that of the rich below 50 -year-old, and then the gap slowly declines towards $10 \%$ for the very old. Next, for simplicity we assume that throughout the period of study the wealth share of the poor is equal to $\operatorname{sh}_{t}^{P}(a)=10 \%$ for all age groups. ${ }^{214}$

Applying these parameters and the above formulas, we obtained ratios $\mathrm{w}_{\mathrm{dt}}(\mathrm{a}) / \mathrm{w}_{\mathrm{t}}(\mathrm{a})$ ratios equal to $73 \%$ below 50 -year-old, and then rising until $96 \%$ for the 80 -year-old and over (see Table B4). I.e. because the poor are over-represented among decedents (especially among young-age decedents), the average wealth of decedents at any given age is below the average wealth of the living (and especially so at young age). Alternatively, one can see that the $w_{t}(a) / w_{d t}(a)$ ratios are above $100 \%$ for all age groups and declining with age, from $136 \%$ below 50 -year-old to $104 \%$ for the 80 -year-old and over (see Table B4). I.e. if one observes the average wealth of decedents of a given age group, then one needs to upgrade this value by a factor ranging from $136 \%$ to $104 \%$ (depending on age) in order to compute the average wealth of the living for this given age group.

[^135]Multiplying this profile of $\mathrm{w}_{\mathrm{t}}(\mathrm{a}) / \mathrm{w}_{\mathrm{dt}}(\mathrm{a})$ ratios by the raw age-wealth-at-death profiles $\mathrm{w}_{\mathrm{dt}}(\mathrm{a})$ reported on Table B3 yields the corrected age-wealth profiles $\mathrm{w}_{\mathrm{t}}(\mathrm{a})$ reported on Table B4. Unsurprisingly, the corrected profiles look less strongly upward-sloping (or more humpshaped, in the immediate postwar period) than the raw profiles: the differential mortality correction leads to increase the wealth of the 50-to-59-year-old relative to the 80-to-89-year-old (because the poor are more massively over-represented in the former group than in the latter).

The way we model differential mortality is relatively standard in the literature, ${ }^{215}$ and is consistent with the best available empirical evidence. In particular, Attanasio and Hoynes (2000) compute mortality rates broken down by wealth quartiles and by age groups. They find that bottom quartile mortality rates are significantly larger than those of other quartiles, and that the mortality ratio is a strongly declining function of age (i.e. differential mortality is larger at low age). The differential mortality parameters used in our computations are directly taken from this paper. ${ }^{216}$ We also tried several alternative formulations (e.g. mortality differentials defined at the wealth quartile level, rather than at the bottom half vs upper half level), but we found that this made very little difference in terms of final $\mu_{\mathrm{t}}$ ratios estimates, and decided that the extra complexity associated to there more sophisticated formulations was not really justified given our purposes in this research.

There is also an issue as to whether the quantitative importance of differential mortality has changed significantly in the long run. Here we simply assumed constant differential mortality parameters over the entire 1820-2006 period. In order to test for the consistency of this assumption, we computed the average age at the death of the poor and the rich predicted by our differential mortality parameters, given observed average mortality rates by cohort since 1820. We found that the predicted age-at-death gap between rich and poor was relatively stable at about 4-5 years over the 1820-2006 period, and that the predicted

[^136]gap between the rich and the average was relatively stable at about 2-3 years, both with a slight downward time trend. ${ }^{217}$ Using estate tax data, we can compute the average age at death of tax filers (i.e. approximately the upper half of the wealth distribution) over the 1906-2006 period, and compare it the average age of decedents. We again find a relatively stable rich vs average gap of about 2 years over the past century. ${ }^{218}$ We conclude from this that our simple assumption of stable differential mortality parameters is acceptable as a first approximation. If anything, we might slightly overstate differential mortality, especially in the recent period, which would imply that our $\mu_{\mathrm{t}}$ ratio is slightly underestimated for the recent decades.

Table B5: Computation of $\mu_{t}$ and $\mu_{t}^{*}$ ratios in France, 1820-2006

On Table B5 we report our estimates for the ratio $\mu_{t}$. By definition, $\mu_{t}$ is the ratio between average wealth of decedents and average wealth of the living, so it can easily be computing by weighting by the relevant population the age-wealth-at-death profiles $\mathrm{w}_{\mathrm{dt}}(\mathrm{a})$ reported on Table B3 and the age-wealth-of-the-living profiles $\mathrm{w}_{\mathrm{t}}(\mathrm{a})$ reported on Table B4, and by dividing one by the other. As we explained in the working paper (section 3.1), we find it more convenient to exclude children from our basic accounting equation relating the aggregate bequest flow to aggregate wealth, which we wrote as follows:

$$
\begin{equation*}
B_{t}=\mu_{t} m_{t} W_{t} \tag{B.6}
\end{equation*}
$$

With: $B_{t}=$ annual bequest flow
$W_{t}=$ aggregate private wealth
$\mathrm{m}_{\mathrm{t}}=$ adult mortality rate $=\mathrm{N}_{\mathrm{dt}}^{20+} / \mathrm{N}_{\mathrm{t}}^{20+}=\left[\sum_{\mathrm{a} \geq 20} \mathrm{~N}_{\mathrm{dt}}(\mathrm{a})\right] /\left[\sum_{\mathrm{a} \geq 20} \mathrm{~N}_{\mathrm{t}}(\mathrm{a})\right]$

We chose to do so because children usually own very little wealth (except in the few cases where they have already inherited). The advantage of this formulation is that this makes both the levels and evolutions of the coefficients $\mu_{t}$ and $m_{t}$ easier to interpret. In particular this allows us to abstract from the large historical variations in infant mortality (which was

[^137]much higher in the $19^{\text {th }}$ century than it is today). However strictly speaking children wealth is not exactly equal to zero (because children sometime inherit), so in order to ensure the full consistency of the accounting equation (B.6) we need to introduce a small correction factor $c f_{t}$ in the definition of the $\mu_{t}$ ratio so as to correct for the existence of positive children wealth. Taking children into account, the accounting equation is actually the following:
\[

$$
\begin{equation*}
\mathrm{B}_{\mathrm{t}}=\mu_{\mathrm{t}}^{0+} \mathrm{m}_{\mathrm{t}}^{0+} \mathrm{W}_{\mathrm{t}} \tag{B.7}
\end{equation*}
$$

\]

Where $\mathrm{m}_{\mathrm{t}}^{0+}=\mathrm{N}_{\mathrm{dt}}{ }^{0+} / \mathrm{N}_{\mathrm{t}}^{0+}=\left[\sum_{\mathrm{a} \geq 0} \mathrm{~N}_{\mathrm{dt}}(\mathrm{a})\right] /\left[\sum_{\mathrm{a} \geq 0} \mathrm{~N}_{\mathrm{t}}(\mathrm{a})\right]$ is the average mortality rate for the entire population (including children), and $\mu_{\mathrm{t}}{ }^{0+}$ is the ratio between average wealth of the deceased and average wealth of the living computed for the entire population (including children), i.e.:

$$
\begin{equation*}
\mu_{\mathrm{t}}^{0+}=\mathrm{w}_{\mathrm{dt}}^{0+} / \mathrm{w}_{\mathrm{t}}^{0+} \tag{B.8}
\end{equation*}
$$

With: $\mathrm{w}_{\mathrm{dt}}{ }^{0+}=\left(\sum_{\mathrm{a} \geq 0} \mathrm{~N}_{\mathrm{dt}}(\mathrm{a}) \mathrm{W}_{\mathrm{dt}}(\mathrm{a})\right) / \mathrm{N}_{\mathrm{dt}}{ }^{0+}=$ average wealth of all decedents (incl. children) $w_{t}^{0+}=\left(\sum_{a \geq 0} N_{t}(a) w_{t}(a)\right) / N_{t}^{0+}=$ average wealth of all living individuals (incl. children)

This differs from the $\mu_{\mathrm{t}}^{20+}$ ratio defined over adults (20-year-old and over):

$$
\begin{equation*}
\mu_{\mathrm{t}}^{20+}=\mathrm{w}_{\mathrm{dt}}{ }^{20+} / \mathrm{w}_{\mathrm{t}}^{20+} \tag{B.9}
\end{equation*}
$$

With: $\mathrm{w}_{\mathrm{dt}}^{20+}=\left(\sum_{\mathrm{a} \geq 20} \mathrm{~N}_{\mathrm{dt}}(\mathrm{a}) \mathrm{w}_{\mathrm{dt}}(\mathrm{a})\right) / \mathrm{N}_{\mathrm{dt}}^{20+}=$ average wealth of adult decedents $\mathrm{w}_{\mathrm{t}}^{20+}=\left(\sum_{\mathrm{a} \geq 20} \mathrm{~N}_{\mathrm{t}}(\mathrm{a}) \mathrm{w}_{\mathrm{t}}(\mathrm{a})\right) / \mathrm{N}_{\mathrm{t}}^{20+}=$ average wealth of adult living individuals

By combining equations (B.6) and (B.7), one obtains a simple formula for the childrenwealth correction factor $\mathrm{cf}_{\mathrm{t}}$ :

$$
\begin{gather*}
\mu_{t}=\mathrm{cf}_{\mathrm{t}} \mu_{\mathrm{t}}^{20+}  \tag{B.10}\\
\text { With: } \quad \mathrm{cf}_{\mathrm{t}}=\left[\mathrm{W}_{\mathrm{t}}^{20+} / \mathrm{W}_{\mathrm{t}}\right] /\left[\mathrm{B}_{\mathrm{t}}^{20+} / \mathrm{B}_{\mathrm{t}}\right] \tag{B.11}
\end{gather*}
$$

With:
$\mathrm{W}_{\mathrm{t}}^{20+}=$ total wealth of adult living individuals $=\sum_{\mathrm{a} \geq 20} \mathrm{~N}_{\mathrm{t}}(\mathrm{a}) \mathrm{W}_{\mathrm{t}}(\mathrm{a})$
$W_{t}=$ total wealth of all living individuals (incl. children) $=\sum_{a \geq 0} N_{t}(a) w_{t}(a)$
$\mathrm{B}_{\mathrm{t}}^{20+}=$ total bequests left by adult decedents $=\sum_{\mathrm{a} \geq 20} \mathrm{~N}_{\mathrm{dt}}(\mathrm{a}) \mathrm{w}_{\mathrm{dt}}(\mathrm{a})$
$\mathrm{B}_{\mathrm{t}}=$ total bequests left by all decedents (incl. children) $=\sum_{\mathrm{a} \geq 0} \mathrm{~N}_{\mathrm{dt}}(\mathrm{a}) \mathrm{w}_{\mathrm{dt}}(\mathrm{a})$
I.e. the correcting factor $\mathrm{cf}_{\mathrm{t}}$ is equal to the ratio between the share of living individuals aged 20-year-old-and-over in aggregate private wealth $\mathrm{W}_{\mathrm{t}}^{20+} / \mathrm{W}_{\mathrm{t}}$ and the share of decedents aged 20 -year-old-and-over in the aggregate bequest flow $\mathrm{B}_{\mathrm{t}}{ }^{20+} / \mathrm{B}_{\mathrm{t}}$. Of course if children own no wealth at all, then both shares are equal to $100 \%$, the correcting factor $\mathrm{cf}_{\mathrm{t}}$ is also equal to $100 \%$, and the $\mu_{\mathrm{t}}$ ratio is simply equal to the $\mu_{\mathrm{t}}{ }^{20+}$ ratio defined over the adult population: i.e. there is no need for a correction factor.

Applying the equations above to the age-wealth-at-death profiles $\mathrm{w}_{\mathrm{dt}}(\mathrm{a})$ and the age-wealth-of-the-living profiles $\mathrm{w}_{\mathrm{t}}(\mathrm{a})$ reported on Tables B3-B4, and to the demographic series $\mathrm{N}_{\mathrm{dt}}(\mathrm{a})$ and $\mathrm{N}_{\mathrm{t}}(\mathrm{a})$ provided in Appendix C, we obtain the series for the various ratios reported on Table B5 (col. (6)-(12)). ${ }^{219}$ As one can see, adult shares are not exactly equal to $100 \%$, but they are very close. According to our computations, the share owned by adults in the aggregate wealth of the living $W_{t}{ }^{20+} / W_{t}$ gradually grew from about $95 \%$ in the $19^{\text {th }}$ century to about $99 \%$ in the early $21^{\text {st }}$ century (see Table B5, col. (10)). The fact that the children wealth share declines over time reflects the fact that children successors have become rarer over time. According to our computations, the share left by adults in aggregate bequest flow $\mathrm{B}_{\mathrm{t}}{ }^{20+} / \mathrm{B}_{\mathrm{t}}$ also grew in the long run, from about $98 \%$ in the $19^{\text {th }}$ century to almost $100 \%$ in the $20^{\text {th }}$ century (see Table B5, col. (9)). The fact that the latter is always somewhat smaller than the former reflects the fact that children leave bequests even more rarely than they receive bequests. Consequently, the correcting factor $\mathrm{cf}_{\mathrm{t}}$ is always slightly smaller than $100 \%$. As expected, it is however very close to $100 \%$ : about $97 \%$ in the $19^{\text {th }}$ century, and about $98 \%-99 \%$ during the $20^{\text {th }}$ century (see Table B5, col. (8)). The children wealth correction factor is virtually irrelevant for our aggregate series. ${ }^{220}$

Multiplying the adult ratio $\mu_{\mathrm{t}}^{20+}$ (col. (7)) by the children correction factor $\mathrm{cf}_{\mathrm{t}}$ (col.(8)), we get our children-corrected ratio $\mu_{\mathrm{t}}$ (col.(11)). We find that $\mu_{\mathrm{t}}$ was about $120 \%-140 \%$ from 1820 to 1913, then dropped to less than $90 \%$ in the immediate postwar period, then gradually increased to over $120 \%$ in the 2000s. Multiplying $\mu_{t}$ by $1+v_{t}$, where $v_{t}$ is the gift-bequest ratio (see section B. 1 above), we get our gift-corrected ratio $\mu_{t}{ }^{*}=\left(1+v_{t}\right) \mu_{t}($ col. (12)). We find

[^138]that $\mu_{t}{ }^{*}$ was about $150 \%-160 \%$ from 1820 to 1913, then dropped to little more than $100 \%$ in the immediate postwar period, then gradually increased to over $220 \%$ in the 2000s. We use these $\mu_{t}{ }^{*}$ series to compute the economic inheritance flow in Appendix A (section A.2).

We also report on Table B5 the ratio between the average wealth of living individuals aged $50-$ to-59-year-old $w_{t}{ }^{50-59}$ and the average wealth of all adults $w_{t}{ }^{20+}$ (see col. (13). Note that the average wealth $w_{t}{ }^{20+}$ is slightly smaller than per adult wealth $w_{t}$, which we defined in Appendix A (Tables A1-A2, col. (8)) as aggregate private wealth $W_{t}$ divided by the number of adults $N_{t}{ }^{20+}: w_{t}^{20+}=w_{t} \times\left[W_{t}^{20+} / W_{t}\right]$. On Table $B 5$ we also report the ratio between $w_{t}^{50-59}$ and per adult wealth $w_{t}$ (see col. (14)). We use it in the simulated model (see Appendix D).

Finally, we also report on Table B5 (col.(1)-(5)) the estimates for the $\mu_{\mathrm{t}}$ ratios that one would obtain under uniform mortality assumptions, i.e. ignoring differential mortality. Col. (1)-(5) of Table B5 were obtained by applying the same formulas as above, but by assuming that the age-wealth-of-the living profile $\mathrm{w}_{\mathrm{t}}(\mathrm{a})$ is the same as the age-wealth-atdeath profile $\mathrm{w}_{\mathrm{dt}}(\mathrm{a}) .{ }^{221}$ As one can see, differential mortality has a strong impact on estimated $\mu_{\mathrm{t}}$ ratios. Under uniform mortality assumptions, the $\mu_{\mathrm{t}}{ }^{20+}$ ratio would be as large as $160 \%-180 \%$ from 1820 to 1913 (instead of $120 \%-130 \%$ under differential mortality assumptions), and would be over $150 \%$ in the 2000s (instead of over 120\%) (see Table B5, col. (2) vs col.(7)). Throughout the period 1820-2006, the $\mu_{\mathrm{t}}$ ratio would be about $25 \%-$ $30 \%$ larger under uniform mortality assumptions. I.e. according to our computations, differential mortality (the fact that the rich dies less often than the poor) makes aggregate bequest flows about $25 \%-30 \%$ lower than they would otherwise be.

[^139]
## Appendix C: Demographic Data

In addition to national accounts data and estate tax data, this research also relies intensively on demographic data. First, at various points we need a relatively complete demographic file with annual numbers of living individuals $N_{t}(a)$ and decedents $N_{d t}(a)$ by exact age and cohort, which we constructed using available historical population tables for the 1820-2009 period and existing population projections for the 2010-2100 period. The way we assembled this basic demographic data base is described in section C1. Next, in order to simulate the age-level dynamics of wealth accumulation and inheritance, we also need relatively complete data on the age structure of decedents, successors, donors and donees. The way we constructed this supplementary data base is described in section C 2 .

## C.1. Basic demographic data (population tables)

We report on Tables C1-C4 a number of demographic series which we use repeatedly in Appendix A and B..$^{222}$ These series are directly extracted from our basic demographic data base, which takes the form of a Stata format data base, which we describe below.

## Notations

We use the same demographic notations as in Appendices $A$ and $B$ :
$N_{t}=$ total living population in France on $1 / 1$ of year $t(t=1820,1821, \ldots, 2100)$.
By convention population is always estimated on $1 / 1$ (January $1^{\text {st }}$ ) of year t .
$\mathrm{n}_{\mathrm{t}}=\mathrm{N}_{\mathrm{t}+1} / \mathrm{N}_{\mathrm{t}}-1=$ population growth rate during year t
$N_{t}$ can be decomposed by birth cohort $x$ :

$$
\begin{equation*}
N_{t}=\sum_{x<t} N_{t}^{x} \tag{C.1}
\end{equation*}
$$

With: $N_{t}{ }^{x}=$ total living population on $1 / 1$ of year $t$ and born during year $x<t$

[^140]Since $N_{t}$ is measured on $1 / 1$ of each year $t$, then by convention $N_{t}{ }^{t}=0$, i.e. nobody is born during year $t$ and alive on $1 / 1$ of year $t$.

Alternatively, $\mathrm{N}_{\mathrm{t}}$ can be decomposed by age group a:

$$
\begin{equation*}
N_{t}=\sum_{a \geq 0} N_{t}(a) \tag{C.2}
\end{equation*}
$$

With: $\mathrm{N}_{\mathrm{t}}(\mathrm{a})=$ total living population aged a-year-old on $1 / 1$ of year t .

By convention, we measure age on $1 / 1$ of each year, so that $a(t, x)=t-x-1$
With: $a(t, x)=$ age on $1 / 1$ of year $t$ of individuals born during year $x$
Alternatively: $\mathrm{x}(\mathrm{t}, \mathrm{a})=\mathrm{t}-\mathrm{a}-1$
E.g. in 1900, the individuals aged 0-year-old are the individuals born during year 1899, the individuals aged 1-year-old are the individuals born during year 1898, etc., and the individuals aged 99-year-old are the individuals born during year 1800.

Due to data limitations, the age distribution is censored at $\mathrm{a}=99$ : the age of all individuals with age $a \geq 99$ is set to $a=99$; the birth cohort all individuals with birth cohort $x \leq t-100$ is set to $\mathrm{x}=\mathrm{t}-100$ (see below).

We also note $N_{t}^{20+}=\sum_{a \geq 20} N_{t}(a)$ the total number of living individuals aged 20-year-old and over on $1 / 1$ of year $t$.

We use similar notations for decedents:
$\mathrm{N}_{\mathrm{dt}}=$ total number of decedents in France during year t
$\mathrm{N}_{\mathrm{dt}}$ can be decomposed by birth cohort x or by age group a:

$$
\begin{equation*}
N_{d t}=\sum_{x \leq t} N_{d t}{ }^{x}=\sum_{a \geq-1} N_{d t}(a) \tag{C.3}
\end{equation*}
$$

With: $\mathrm{N}_{\mathrm{dt}}{ }^{\mathrm{x}}=$ number of individuals born during year x and deceased during year t
$N_{\mathrm{dt}}(\mathrm{a})$ = number of individuals aged a-year-old on $1 / 1$ of year $\mathrm{t}(\mathrm{a}=\mathrm{t}-\mathrm{x}-1)$ and deceased during year $t$
$\mathrm{N}_{\mathrm{dt}}^{20+}=\sum_{\mathrm{a} \geq 20} \mathrm{~N}_{\mathrm{dt}}(\mathrm{a})=$ total number of individuals aged 20-year-old on $1 / 1$ of year $\mathrm{t}(\mathrm{a}=\mathrm{t}-\mathrm{x}-1)$ and deceased during year $t$

Note that $N_{d t}{ }^{t}=N_{\mathrm{dt}}(-1)>0$ : these are the individuals born during year t and deceased during year $t$ (such individuals are therefore not counted in populations $N_{t}$ or $N_{t+1}$ ).

We can then define mortality rates:

$$
\begin{equation*}
\mathrm{m}_{\mathrm{t}}=\mathrm{N}_{\mathrm{dt}}^{20+} / \mathrm{N}_{\mathrm{t}}^{20+}=\sum_{\mathrm{a} \geq 20} \mathrm{~N}_{\mathrm{dt}}(\mathrm{a}) / \sum_{\mathrm{a} \geq 20} \mathrm{~N}_{\mathrm{t}}(\mathrm{a}) \tag{C.4}
\end{equation*}
$$

(= aggregate mortality rate of individuals aged 20-year-old and above during year t)

$$
\begin{equation*}
m_{t}^{0+}=N_{d t} / N_{t}=\sum_{a \geq-1} N_{d t}(a) / \sum_{a \geq 0} N_{t}(a) \tag{C.5}
\end{equation*}
$$

(= aggregate mortality rate of the entire population (including the population aged 0 to 19-year-old) during year t)

$$
\begin{equation*}
m_{t}^{x}=N_{d t}{ }^{\mathrm{x}} / \mathrm{N}_{\mathrm{t}}^{\mathrm{x}} \tag{C.6}
\end{equation*}
$$

(= mortality rate of birth cohort $x$ during year $t$ )

$$
\begin{equation*}
m_{t}(a)=N_{d t}(a) / N_{t}(a) \tag{C.7}
\end{equation*}
$$

(= mortality rate of individuals aged a-year-old during year $t$ )

We use similar notations for birth and migrants.
$N_{b t}=$ total number of births in France during year $t$
$f_{t}=N_{b t} / N_{t}=$ fertility rate in France during year $t$
$N_{\text {it }}=$ net number of immigrants entering France during year $t$
$N_{i t}=\sum_{x \leq t} N_{i t}{ }^{x}=\sum_{a \geq-1} N_{i t}(a)$
With: $\mathrm{N}_{\mathrm{it}}{ }^{\mathrm{x}}=$ net number of immigrants born during year x and entering during year t
$N_{i t}(a)=$ net number of immigrants aged a-year-old on $1 / 1$ of year $t(a=t-x-1)$ and entering during year t
$\mathrm{i}_{\mathrm{t}}=\mathrm{N}_{\mathrm{it}} / \mathrm{N}_{\mathrm{t}}=$ net migration rate during year t
$\mathrm{i}_{\mathrm{t}}^{\mathrm{x}}=\mathrm{N}_{\mathrm{it}}{ }^{\mathrm{x}} / \mathrm{N}_{\mathrm{t}}^{\mathrm{x}}=$ net migration rate of birth cohort x during year t
$\mathrm{i}_{\mathrm{t}}(\mathrm{a})=\mathrm{N}_{\mathrm{it}}(\mathrm{a}) / \mathrm{N}_{\mathrm{t}}(\mathrm{a})=$ net migration rate of individuals aged a-year-old during year t

By construction, our data base is dynamically consistent:

$$
\begin{equation*}
N_{t+1}=N_{t}+N_{b t}-N_{d t}+N_{i t} \tag{C.8}
\end{equation*}
$$

l.e. $n_{t}=f_{t}-m_{t}+i_{t}$
(population growth rate $=$ fertility rate - mortality rate + net migration rate)

Similarly, by birth cohort:
For t-99<x<t, $N_{t+1}{ }^{x}=N_{t}{ }^{x}-N_{d t}{ }^{x}+N_{i t}{ }^{x}$
For $\mathrm{x}=\mathrm{t}, \mathrm{N}_{\mathrm{t}+1}{ }^{\mathrm{x}}=\mathrm{N}_{\mathrm{bt}}-\mathrm{N}_{\mathrm{dt}}{ }^{\mathrm{t}}+\mathrm{N}_{\mathrm{it}}{ }^{\mathrm{x}}$
For $\mathrm{x}=\mathrm{t}-99, \mathrm{~N}_{\mathrm{t}+1}{ }^{\mathrm{x}}=\mathrm{N}_{\mathrm{t}}^{\mathrm{x}}+\mathrm{N}_{\mathrm{t}}^{\mathrm{x}-1}-\mathrm{N}_{\mathrm{dt}}{ }^{\mathrm{x}}-\mathrm{N}_{\mathrm{dt}}{ }^{\mathrm{x}-1}+\mathrm{N}_{\mathrm{it}}{ }^{\mathrm{x}}+\mathrm{N}_{\mathrm{it}}^{\mathrm{x}-1}$

Or, alternatively, by age group:
For $0<a<99, N_{t+1}(a)=N_{t}(a-1)-N_{d t}(a-1)+N_{i t}(a-1)$
For $a=0, N_{t+1}(a)=N_{b t}-N_{d t}(a-1)+N_{i t}(a-1)$
For $\mathrm{a}=99, \mathrm{~N}_{\mathrm{t}+1}(\mathrm{a})=\mathrm{N}_{\mathrm{t}}(\mathrm{a}-1)+\mathrm{N}_{\mathrm{t}}(\mathrm{a})-\mathrm{N}_{\mathrm{dt}}(\mathrm{a}-1)-\mathrm{N}_{\mathrm{dt}}(\mathrm{a})+\mathrm{N}_{\mathrm{it}}(\mathrm{a}-1)+\mathrm{N}_{\mathrm{it}}(\mathrm{a})$

## Raw data sources for 1900-2050

The raw data for our demographic data base comes primarily from Insee official population tables for the 1900-2007 period and Insee official population projections for the 2008-2050 period. We then extended this 1900-2050 data base to the past (down to 1820) and to the future (up to 2100) (see below).

Current population tables are published every year by Insee. ${ }^{223}$ Complete retrospective 1900-2007 population tables for living individuals $N_{t}(a),{ }^{224}$ for decedents $N_{d t}(a),{ }^{225}$ and for births $N_{b t}$, are easily available on-line. ${ }^{226}$

[^141]Note that all these population and demographic series refer to mainland France (i.e. excluding overseas territories), and more specifically to the historical territory of mainland France, i.e. the current territory for the 1820-1870, 1920-1938 and 1946-2007 periods, and the current territory minus Alsace-Moselle for the 1871-1919 and 1939-1945 periods. This territorial change explains the large population growth in 1920 and 1946, and the large fall in 1871 and 1939 (see Table C1). Note also that migration figures are to a large extent residual estimates, and should be used with caution, especially during the war years. ${ }^{227}$

Overall, the only missing data for the 1901-2007 period is the data on the age structure of the living population for the 1915-1919 period. We completed this missing data by using the data on the age structure of the living population for 1914, the age structure of decedents for the 1914-1918 period, the number of births for the 1914-1918, and by assuming zero migration during the 1914-1918 period. In effect, this is assuming that all cumulated migrations during the 1914-1919 period occurred in year 1919. This approximation has no impact on subsequent years.
$\sum_{\mathrm{az}-1} \mathrm{~N}_{\mathrm{dt}}(\mathrm{a})$ ) is "Tableau 6: Population totale par sexe, âge et état matrimonial au 1er janvier ...". The relevant table for the the age structure of decedents ( $N_{\mathrm{dt}}=\sum_{x \leq t} N_{\mathrm{dt}}{ }^{\times}=\sum_{\mathrm{az}-1} N_{\mathrm{dt}}(\mathrm{a})$ ) is "Tableau 71: Décès par sexe, année de naissance, âge et état matrimonial du décédé".
${ }^{224}$ The full set of retrospective tables for the living population covering the 1901-2007 period (with the exception of years 1915-1919) is available on-line at www.insee.fr.
${ }^{225}$ The tables for decedents are also available on-line at www.insee.fr, but only since 2002. For previous years we used the Vallin-Mesle data base on decedents. This data base is available on-line at www.ined.fr, and is fully consistent with the more recent Insee tables. See J. Vallin and F. Mesle, "Décès par âge et par génération, de 1899 à 1997 » (www.ined.fr). One additional advantage of the Vallin-Mesle data base is that they attempt to include all decedents during war years (while Insee official estimates only refer to civilian decedents). For the 1997-2002 period we used the decedents tables published in the paper publications "La situation démographique en ...".
${ }^{226}$ See "Un siècle de fécondité française" (INSEE-Résultats juin 2007, Société ${ }^{\circ} 66$, www.insee.fr). This publication includes updated series from F. Daguet, "Un siècle de fécondité française, Caractéristiques et évolution de la fécondité de 1901 à 1999", 2002, INSEE Résultats, Société $n^{\circ} 8,2002$. Table 35 of this publication provides 1901-2007 series on the number of births broken down by gender. However these series refer to the current territory (as opposed to the historical territory) for the 1901-1919 and 1939-1945 periods. So in order to make these series consistent with the series on living population and decedents, we did the following. For 1901-1913 and 1939-1945, we used the historical-territory total number of births reported on table 1.1B, and we assumed that the gender decomposition of births reported on table 35 for the current territory also applied to the historical territory. For 1914-1919, the total number of births reported on table 1.1B was not usable (it refers to an even smaller territory), so we had to estimate the total number of births assuming that the $94.4 \%$ (historical territory)/(current territory) ratio observed in 1913 also applied to 1914-1919 (in practice, this ratio is pretty stable around $94 \%-95 \%$ ); we also assumed that the gender decomposition of births reported on table 35 for the current territory applied to the historical territory.
${ }^{227}$ Like most statistical institutes, Insee independently computes living population estimates from censuses and household surveys, while decedents and birth estimates come from administrative, etat-civil data; although direct sources on migrations are also used for control purposes, aggregate migration figures are basically obtained by differentiating these two sources.

Regarding the 2008-2050 period, we used the latest official population projections, which were published by INSEE in 2007, mostly for pension planning purposes. ${ }^{228}$ These projections include a full set of annual tables on the age structure of the living population and decedents and on births. This set of projected population tables for 2008-2050 is also available on-line, ${ }^{229}$ and is fully consistent with the pre-2008 demographic series. ${ }^{230}$

Finally, because the raw data uses varying top age censoring over the 1900-2050 period (from 100 to 120), we recoded all the series using a uniform maximum age a=99. I.e. the age of all individuals with age $a \geq 99$ was set to $a=99$, the birth cohort all individuals with birth cohort $\mathrm{x} \leq \mathrm{t}-100$ is set to $\mathrm{x}=\mathrm{t}-100$, and we assumed zero migration for this age group. In effect, the age group ( $a=99, x=t-100$ ) is a terminal point where individuals can spend several years. Given the relatively small numbers of individuals involved, and the very high annual mortality rate for this category (from about $50 \%$ in the early $20^{\text {th }}$ century to about $30 \%$ in the early $21^{\text {st }}$ century), this approximation is innocuous for our purposes.

Resulting data base 1900-2050 and extension to 1820-2100

The data base resulting from official population tables and projections takes the form of a rectangular Stata file pop19002050.dta. At various points in this research, and particularly for the simulations, we also need population projections running until year 2100, and a population data base starting in 1820. We used an extended population file pop18202100.dta, which was obtained from file pop19002050.dta by assuming that aggregate fertility and age-level mortality rates and migration rates remain the same during the 2050-2100 as those projected for 2050, and by using available mortality tables and birth data prior to 1900. All details are provided in the do-file dopopulation18202100.txt, which transforms the basic population file pop19002050.dta into the extended population file pop18202100.dta. According to these future projections, French population will be almost stationary after 2050, with total population rising from 70.2 millions in 2050 to 72.2 millions in 2100. Our 1820-1900 data replicates by construction observed total population

[^142]during the $19^{\text {th }}$ century ( 30.3 millions in 1820 , 35.4 millions in 1850 , vs 38.5 millions in 1900) and observed trends in mortality rates by age group. However, because raw mortality data is not available at the age level prior to 1900 (we had to use raw mortality rates for 5 -year-wide age groups), our demographic data base is less precise for the pre1900 period, especially for the early cohorts born during the $18^{\text {th }}$ century (annual fertility data starts in 1800 in France, so we do not know very precisely the size of earlier cohorts). ${ }^{231}$

We use the population file pop18202100.dta as background demographic data at various points in this paper. In particular, by applying the do-file dotableC1.txt to this data base, one can obtain the summary statistics on population growth and mortality rates reported on Table C1. By applying the do-files dotableC3-C4.txt, one can obtain the summary statistics on the age structure of living individuals and of decedents reported on Tables C3 and C4.

The population file pop19002050.dta contains 15,251 observations (151 years x 101 cohorts $=15,250$ year $x$ cohort pairs) and 15 variables.

The population file pop18202100.dta contains 25,351 observations ( 281 years $\times 101$ cohorts $=28,381$ year $x$ cohort pairs) and 15 variables.

The list of 15 variables is the following:
year $=t=1900,1901, \ldots, 2050=$ year of observation
cohort $=\mathrm{x}=$ year of birth of the cohort under consideration; for a given year, cohort takes the following values: year-100, year-99,..., year. I.e. in year = 1900, we observe cohorts born in cohort = 1800, 1801, $\ldots, 1900$.
age $=\mathrm{a}=\mathrm{t}-\mathrm{x}-1=$ year - cohort $-1=$ age a on $1 / 1$ of the year. I.e. age $=-1,0,1, ., 99$

[^143]ntot $=N_{t}{ }^{\mathrm{x}}=$ number of individuals born during year x and alive on $1 / 1$ of year t
nmen $=$ number of male individuals born during year x and alive on $1 / 1$ of year t
nwomen $=$ number of female individuals born during year $x$ and alive on $1 / 1$ of year $t$
$n d e c=N_{d t}{ }^{\mathrm{x}}=$ number of individuals born during year x and deceased during year t
ndecmen =number of male individuals born during year $x$ and deceased during year $t$
ndecwomen =number of female indiv. born during year x and deceased during year t
nbirth $=\mathrm{N}_{\mathrm{bt}}=$ total number of births during year t
nbirthmen = total number of male births during year t
nbirthwomen $=$ total number of female births during year $t$
$n m i g r=\mathrm{N}_{\mathrm{it}}{ }^{\mathrm{x}}=$ net number of individuals born during year x and migrating to France during year $t$ (i.e. living in France on $1 / 1 \mathrm{t}+1$ and not living in France on $1 / 1 \mathrm{t}$ )
nmigrmen $=$ net number of male individuals born during year x and migrating to France during year $t$
nmigrwomen $=$ net number of female individuals born during year x and migrating to France during year t

## C.2. Supplementary data on age of decedents, heirs, donors and donees

In order to simulate the age-level dynamics of wealth accumulation and inheritance, we need relatively complete data not only on the age structure of decedents, but also on the age structure of heirs (the successors receiving bequests from decedents), donors (the living individuals making inter vivos gifts) and donees (the living individuals receiving inter vivos gifts). This information is not available in standard demographic data, so we had to
construct our own data base. Some of raw material and resulting series are reported on Tables C5 to C8. The complete data base is available in the form of Stata format data sets bequestshares.dta and giftshares.dta. Here we describe how we constructed these data sets.

## Estimating the age structure of decedents and heirs

The annual inheritance flow $B_{t}$ can be decomposed in two different ways, either from the decedents' or from the heirs' perspective:

$$
\begin{equation*}
B_{t}=\sum_{x \leq t} B_{t}{ }^{x}=\sum_{y \leq t} B_{t y} \tag{C.9}
\end{equation*}
$$

With: $B_{t}=$ total inheritance flow transmitted/received during year $t$
$B_{t}{ }^{\mathrm{x}}=$ inheritance flow transmitted during year t by cohort $\mathrm{x} \leq \mathrm{t}$
$B_{\text {ty }}=$ inheritance flow received during year $t$ by cohort $y \leq t$

The decedents decomposition $B_{t}=\sum_{x \leq t} B_{t}{ }^{x}$ is known from estate tax data (see Appendix B2). However the heirs decomposition $B_{t}=\sum_{y s t} B_{t y}$ is harder to estimate. Ideally, one would like to have systematic demographic data base relating directly the cohort of the decedents and the cohort of the heirs. I.e. one would like to know for each decedents' cohort x the distribution of heir's cohorts $\mathrm{y}(\mathrm{x})$. Unfortunately, it seemed overly complicated to estimate such distributions on an annual basis over two centuries. Because not all heirs are children, purely demographic data is not enough: one needs very detailed data from estate tax returns. We actually do have individual-level data relating decedents' cohorts and heirs' cohorts in a systematic way for the recent period, thanks to the DMTG microfiles 1977-1984-1987-1994-2000-2006. But no such data exists for the earlier periods. The estate tax statistics published by the tax administration during the 1902-1964 period include tabulations by decedents age (see Appendix B2), but never include tabulations by heirs age (not to mention cross-tabulations by decedents age and heirs age). Therefore we decided to adopt a more modest strategy, namely we estimated the decomposition $\mathrm{B}_{\mathrm{t}}$ $=\sum_{y s t} B_{t y}$ without attempting to relate directly which decedents cohort gives to which heirs cohorts. I.e. we took as given the aggregate inheritance flow $B_{t}$, and estimated the shares bshare $e_{t y}=B_{t y} / B_{t}$ of aggregate inheritance flow received by each cohort $y \leq t$. There are several steps in our estimation strategy.

First, available demographic data on fertility shows that the average age at which men and women have children has been relatively stable since the $19^{\text {th }}$ century, around 33 -year-old for men and around 29-year-old for women (see Table C5, col. (1) and (2)). ${ }^{232}$ Available fertility data published by Insee also provides for each female cohort starting in 1870 the full distribution of fertility rates broken down by female age. ${ }^{233}$ We used this detailed data to compute the average age of parenthood as a function of parental year of birth (see Table C5, col. (4) and (5)), and as a function of parental year of death (see Table C5, col. (6) and (7)). ${ }^{234}$ This detailed data also shows that the standard deviation of the distribution of age at parenthood has been fairly stable over the $20^{\text {th }}$ century, around $5.5-6.5$ years. ${ }^{235}$

Next, we used this data to compute the evolution of the average age of children heirs at the time their parents die (see Table C6, col. (4)-(6)), and the average age difference between parents and children heirs at the time of inheritance (see Table C6, col. (8)). ${ }^{236}$ Unsurprisingly, we find that the average age difference has been relatively stable around 30 years: average age of decedents has gone up from about 60-year-old in 1900 to 75-year-old in 2000 and 85 -year-old by 2050, while the average age of children heirs has gone up from about 30-year-old in 1900 to 45-year-old in 2000 and 55-year-old by 2050 (see Table C6). Unsurprisingly, children heirs tend to be older when they inherit from their mothers than when they inherit from their fathers, simply because the former tend to die later (and also because they tend to have children at an earlier age). Note that although these computations are based solely upon pure demographic data, they deliver estimates of average age of children heirs which are fully consistent with the estimates one can obtain using the DMTG micro-files of estate tax returns available for the recent period. ${ }^{237}$

[^144]Finally, available estate tax data shows that the fraction of the aggregate inheritance flow $\mathrm{B}_{\mathrm{t}}$ received by children has been relatively stable over the $20^{\text {th }}$ century, around $70 \%$. More precisely, if we divide heirs into three categories, i.e. children, surviving spouses, and other heirs, then we find that the decomposition of the aggregate inheritance flow $B_{t}$ into these three categories has been relatively stable around $70 \%$ for children, $10 \%$ for spouses, and $20 \%$ for others. ${ }^{238}$ This is true both when we compute this decomposition using the DMTG micro-files 1984-1987-1994-2000 and when we use the available tabulations by heir category published by the tax administration during the 1902-1964 period. There are slight variations in this decomposition, but there is no clear trend, and given that this data is available for a limited number of years, it seems pointless to attempt to give precise estimates of the time variations of this decomposition. ${ }^{239}$

We therefore proceed in the following manner. We estimate the average age of all heirs (see Table C6, col. (7)) by computing a weighted average of the average age of children heirs (with weight $70 \%$ ), the average age of surviving spouses (with weight $10 \%$ ), and the average age of other heirs (with weight 20\%). In the absence of better data, we assumed the average age difference between decedents and surviving spouses to be equal to 7 years (this is the stable difference observed with the 1984-2000 DMTG micro-files), ${ }^{240}$ and the average age difference between decedents and other heirs to be equal to 20 years (this is the stable difference observed with the 1984-2000 DMTG micro-files). By construction, this method delivers series on average age of heirs that are fully consistent with those observed in DMTG micro files over the 1984-2006 period. ${ }^{241}$ For the rest of the

[^145]period, one would need to gather relatively sophisticated demographic data (data on the distribution of age differences at marriage, on the age patterns of remarriage, on the distribution of age difference with siblings and nephews/nieces, not to mention the heirs that are fully exterior to the extended family) in order to detect possible historical changes in the pattern of age difference between decedents and surviving spouses and other heirs. Given that we are primarily concerned with aggregate trends, and given that the remaining uncertainty can only affect a relatively small part of the aggregate estate flow (70\% of the flow goes to children, on which we have very reliable information), we felt that this was not worth it. Our resulting estimates show that the average age difference between decedents and heirs has been stable around 25 years, as opposed to 30 years if one only considers children heirs (see Table C6, col. (8)-(9)).

We use the same methodology to estimate the full distribution of heirs age. That is, we estimated separately the distributions bshare ${ }_{\text {ty }}{ }^{c}$, bshare $_{\text {ty }}{ }^{\text {s }}$, bshare $_{\text {ty }}{ }^{\circ}$ using DMTG microfiles, and we then computed then computed the distribution bshare ${ }_{\text {ty }}$ as a weighted average of the three distributions:

$$
\begin{equation*}
\text { bshare }_{\text {ty }}=0.7 \text { bshare }_{\text {ty }}{ }^{\mathrm{c}}+0.1 \text { bshare }_{\mathrm{ty}}{ }^{\mathrm{s}}+0.2 \text { bshare }_{\text {ty }}{ }^{\circ} \tag{C.10}
\end{equation*}
$$

With: bshare ${ }_{t y}=B_{t y} / B_{t}=$ fraction of aggregate inheritance flow received by cohort $y$ bshare ${ }_{\text {ty }}{ }^{c}=$ fraction of the children inheritance flow received by cohort y bshare ${ }_{\text {ty }}{ }^{5}=$ fraction of the spouse inheritance flow received by cohort y bshare $_{\text {ty }}{ }^{\circ}=$ fraction of the other inheritance flow received by cohort $y$

According to the DMTG 1984-2000 micro-files, the three distributions bshare ${ }_{\text {ty }}{ }^{\text {c }}$, bshare $_{\text {ty }}{ }^{s}$, bshare ${ }_{\text {ty }}{ }^{\circ}$ follow relatively simple and stable functional forms approximately centered around their respective mean. Regarding children we find that the best fit is obtained with the following functional form:

$$
\begin{equation*}
\text { bshare }_{\mathrm{ty}}{ }^{\mathrm{c}}=\text { bshare }_{\mathrm{t}}{ }^{\mathrm{c}}(\mathrm{a})=\mathrm{b}^{\mathrm{cmaxt}} /\left[1+\left(\left(\mathrm{a}-\mathrm{a}_{\mathrm{t}}^{\mathrm{c}}-\mathrm{a}^{0 \mathrm{c}}\right) / \mathrm{a}_{\mathrm{sd}}{ }^{\mathrm{c}}\right)^{\delta \mathrm{c}}\right] \tag{C.11}
\end{equation*}
$$

with: $a=t-y-1=$ age of cohort $y$ at time $t$

[^146]$a_{t}^{c}=$ average age of children heirs at time $t$
and where $b^{c m a x t}, a_{s d}{ }^{c}, a^{0 c}, \delta_{c}$ are parameters satisfying the following condition: $\sum_{0 \leq a \leq 80}$ bshare $_{t}^{c}(\mathrm{a})=1$

The parameters minimizing the average age-level gap with the observed distributions turn out to be the following: $a_{s d}{ }^{c}=14.3, a^{0 c}=2.5, \delta_{c}=3$, and $b^{\text {cmaxt }}$ computed each year so as to meet condition $\sum_{0 \leq a \leq 80}$ bshare $_{t}{ }^{c}(a)=1$ (in practice $b^{\text {cmaxt }}$ is always very close to $3.1 \%$ ). ${ }^{242}$

Regarding spouses and other heirs, we use similar functional forms:

$$
\begin{equation*}
\text { bshare }_{\text {ty }}{ }^{s}=\text { bshare }_{t}^{s}(a)=b^{\text {smaxt }} /\left[1+\left(\left(a-a_{t}^{s}-a^{0 s}\right) / a_{s d}^{s}\right)^{\delta s}\right] \tag{C.12}
\end{equation*}
$$

with: $a_{t}^{s}=$ average age of spouse heirs at time $t$
and where $b^{\text {smaxt }}, a_{s d}{ }^{s}, a^{0 s}, \delta_{s}$ are parameters satisfying the condition $\sum_{20 \leq a \leq 99}$ bshare $_{t}{ }^{s}(a)$ $=1$. The gap minimizing parameters are: $a_{s d}{ }^{s}=16.0, a^{0 c}=-1.0, \delta_{s}=4$, and $b^{\text {smaxt }}$ computed each year so as to meet condition $\sum_{20 \leq a \leq 99}$ bshare $_{t}^{s}(a)=1$ (in practice $b^{\text {smaxt }}$ is always very close to $2.9 \%$ ).

$$
\begin{equation*}
\text { bshare }_{\text {ty }}{ }^{\circ}=\text { bshare }_{t}{ }^{\circ}(a)=b^{\text {omaxo }} /\left[1+\left(\left(a-a_{t}^{0}-a^{00}\right) / a_{s d}{ }^{0}\right)^{\delta 0}\right] \tag{C.13}
\end{equation*}
$$

with: $a_{t}{ }^{0}=$ average age of spouse heirs at time $t$
and where $b^{o m a x o}, a_{s d}{ }^{\circ}, a^{00}, \delta_{o}$ are parameters satisfying the condition $\sum_{0 \leq a \leq 99}$ bshare $_{t}{ }^{\circ}(a)$ $=1$. The gap minimizing parameters are: $a_{s d}{ }^{0}=20.0, a^{00}=5.5, \delta_{0}=3.5, b^{\text {omaxt }}$ computed each so as to meet condition $\sum_{0 \leq a \leq 99}$ bshare $_{t}{ }^{\circ}(a)=1$ (in practice $b^{\text {cmaxt }}$ close to $2.3 \%$ ).

The details of the computations are given in the do-file dobequestshares.txt, and the resulting series are given in the Stata file bequestshares.dta.

## Estimating the age structure of donors and donees

[^147]We also use similar computations to estimate the distribution of donors and donees age. Inter vivos gifts are relatively simpler to deal with than bequests, because the recipients of gifts are almost exclusively children. ${ }^{243}$ Moreover, available estate tax data shows the average age of donors has always been about 7 years below the average age of decedents (see Table C7), so we make this assumption for the entire 1900-2050 period (see Table C8, col. (1)). ${ }^{244}$ Using DMTG 1984-2000 micro-files, we adopt the following functional form for the distribution of donors age:

$$
\begin{equation*}
\text { donor }_{t y}=\text { donor }_{t}(\mathrm{a})=\text { donor }^{\text {maxt }} /\left[1+\left(\left(\mathrm{a}-\text { adonor }_{\mathrm{t}}-\mathrm{a}^{\text {donor }}\right) / \mathrm{a}_{\mathrm{sd}}^{\text {donor }}\right)^{\text {סdonor }}\right] \tag{C.14}
\end{equation*}
$$

with: donor ${ }_{\text {ty }}=$ share of total gift flow at time $t$ given by donors from cohort $y$
$\mathrm{a}=\mathrm{t}-\mathrm{y}-1=$ age of cohort y at time t
adonor $_{t}=$ average age of donors at time $t$
and where donor ${ }^{\text {maxt }}, \mathrm{a}_{\mathrm{sd}}{ }^{\text {donor }}, \mathrm{a}^{\text {Odonor }}, \delta_{\text {donor }}$ are parameters satisfying the condition $\sum_{0 \leq a \leq 99}$
donor $_{t}(\mathrm{a})=1$

The parameters minimizing the average age-level gap with the observed distributions turn out to be the following: $a_{\text {sd }}{ }^{\text {donor }}=12.0, a^{\text {Odonor }}=0.5, \delta_{\text {donor }}=5.0$, and donor ${ }^{\text {maxt }}$ computed each year so as to meet condition $\sum_{0 \leq a \leq 99}$ donor $_{t}(a)=1$ (in practice donor ${ }^{m a x t}$ is always very close to $3.9 \%$ ).

Regarding donees age, available estate tax data shows the difference with average donors age is unsurprisingly very close to the average age at parenthood for the relevant donors' cohorts, so we make this assumption for the entire 1900-1950 period (see Table C8, col.(2)). ${ }^{245}$ Using DMTG 1984-2000 micro-files, we adopt the following functional form for the distribution of donees age:

[^148]\[

$$
\begin{equation*}
\text { donee }_{t y}=\text { donee }_{t}(\mathrm{a})=\text { donee }^{\mathrm{maxt}} /\left[1+\left(\left(\mathrm{a}-\text { adonee }_{\mathrm{t}}-\mathrm{a}^{\text {donee }}\right) / \mathrm{a}_{\mathrm{sd}}{ }^{\text {donee }}\right)^{\text {סdonee }}\right] \tag{C.15}
\end{equation*}
$$

\]

with: donee $\mathrm{e}_{\mathrm{ty}}=$ share of total gift flow at time t received by donees from cohort y
$a=t-y-1=$ age of cohort $y$ at time $t$
adonee $_{\mathrm{t}}=$ average age of donees at time t
and where donee ${ }^{\text {maxt }}, a_{\text {sd }}{ }^{\text {donee }}, a^{\text {Odonee }}, \delta_{\text {donee }}$ are parameters satisfying the condition $\sum_{0 \leq a \leq 99}$ donee $_{\mathrm{t}}(\mathrm{a})=1$

The parameters minimizing the average age-level gap with the observed distributions turn out to be the following: $a_{s d}{ }^{\text {donee }}=12.0, a^{\text {Odonee }}=0.0, \quad \delta_{\text {donee }}=3.5$, and donee ${ }^{\text {maxt }}$ computed each year so as to meet condition $\sum_{0 \leq a \leq 99}$ donee $_{t}(a)=1$ (in practice donee ${ }^{\text {maxt }}$ is always very close to $3.7 \%$ ).

The details of the computations are given in the do-file dogiftshares.txt, and the resulting Stata file is giftshares.dta. Note that these estimates of the average of donors and donees also allow us to compute the average of "givers" (decedents and donors) and "receivers" (heirs and donees) for any given year, simply by weighting the relevant age averages by the (gift flow)/(bequest flow) aggregate ratio. Given the large increase in the gift/bequest aggregate ratio during the 1980s-1990s (see Appendix B, Table B1), the average age of "receivers" appears to have stabilized during this period (see Table C8, col. (5)). Post2008 series on Table C8 (col. (5) to (7)) were computed assuming the gift/bequest ratio remains constant after 2008, which of course is uncertain (we explore this further in Appendix D).

Note that although we used this same methodology to compute age-level bequest shares and gift-shares for the entire 1820-2100 period, it is clear that the $19^{\text {th }}$ century and early $20^{\text {th }}$ century estimates rely on a number of approximations. In particular, the assumption of a constant age gap between decedents and donors throughout the period is probably not valid in the very long run. E.g. our series indicate that donees were very young in the early

[^149]$19^{\text {th }}$ century (less than 20 -year-old on average, see Table C8), which is probably an exaggeration. We return to this in the simulations.

## C.3. List of Stata format data files and do-files

pop19002050.dta : basic population data file containing numbers of living individuals and decedents by year and birth cohort
pop18202100.dta: population date file extended to the 1820-2100 period
dopop18202100.txt: do-file generating pop19002050.dta from pop18502100.dta
dotableC1.txt and dotableC3-C4.txt: do-files generating Tables C1 and C3-C4 from pop18202100.dta
ageatbirth.dta: data file with series on parental age at the birth of their children
dotableC5.txt and dotableC6.txt : do-file generating Table C5 from pop18202100.dta and ageatbirth.dta
bequestshares.dta and giftshares.dta: data files containing estimates of the shares of aggregate bequest and gift flows received by each cohort
dobequestshares.txt and dogiftshares.txt: do-files generating bequestshares.dta and giftshares.dta from pop18202100.dta and ageatbirth.dta
dotableC8.txt: do-file generating Table C8 from giftshares.dta
dodiffmort.txt = do-file generating poor vs rich average age at death implied by differential mortality parameters (using data file pop18502100.dta) ${ }^{246}$

[^150]
## Appendix D: Simulations

In this appendix we present the results of our simulations of the age-level dynamics of wealth accumulation and inheritance. The main conceptual issues and conclusions related to these simulations are presented in the working paper (sections 6 and 7 ). Here we provide additional information about the methodology and we present the detailed results.

The transition equations and simulation parameters are presented in section D1. The simulation results under various variants are described separately for the 1820-1913 period (section D3) and the 1900-2100 period (section D4). We then present supplementary simulation results on the structure of lifetime resources by cohort (section D5) and on the share of capitalized and non-capitalized inheritance in aggregate wealth accumulation (section D6).

## D.1. Transition equations and simulation parameters

The basic principle of our simulations is the following. We start from the observed agewealth profile $w_{t}(a)$ for a given base year $t=t_{0}$ (in practice, either $t_{0}=1820$ or either $t_{0}=1900$ ). We then write down a transition equation for age-level wealth $w_{t}(a)$. We want to know whether we can correctly predict the future evolution of the age-wealth profile and of the aggregate inheritance flow. By construction, since we use the observed rates of aggregate savings (and capital gains), we always predict perfectly well the evolution of aggregate private wealth. The name of the game is to see whether simple assumptions on saving behaviour (such as uniform savings or class savings) can also allow us to correctly predict the age structure of wealth, and therefore the macroeconomic magnitude of inheritance flows, via the $\mu_{\mathrm{t}}$ effect. More precisely, the transition equation can be written as follows:

$$
\begin{align*}
W_{t+1}(a+1)= & \left(1+q_{t+1}\right)\left[W_{t}(a)+s_{L t} Y_{L t}(a)+s_{K t} r_{t} W_{t}(a)+d_{t} W_{t}(a)\right] \\
& -B_{t}^{\top}(a)+B_{t}^{R}(a)-V_{t}^{\top}(a)+V_{t}^{R}(a) \tag{D.1}
\end{align*}
$$

With:
$W_{t}(a)=$ aggregate wealth of individuals of age a at time $t$
$W_{t}(a)=W_{t}(a) / N_{t}(a)=$ average wealth of individuals of age at time $t$
$Y_{L t}(a)=$ aggregate labor income of individuals of age $a$ at time $t$
$y_{L t}(a)=Y_{L t}(a) / N_{t}(a)=$ average labor income of individuals of age a at time $t$
$B_{t}{ }^{\top}(a)=$ aggregate bequest flow transmitted by individuals of age a at time $t$
$B_{t}^{R}(a)=$ aggregate bequest flow received by individuals of age $a$ at time $t$
$V_{t}{ }^{\top}(a)=$ aggregate inter vivos gift flow transmitted by individuals of age a time $t$ $V_{t}^{R}(a)=$ aggregate inter vivos gift flow received by individuals of age a at time $t$

The simulation parameters are reported on Tables D1 and D3-D4. These parameters were converted into Stata format data files simulationparameters18201913.dta and simulationparameters19002100.dta. The do-files dosimul18201913.txt and dosimul19002100.txt use these data files, together with the demographic data files described in Appendix C, in order to generate the simulation results reported on Tables D5-D6. In principle all results can be easily reproduced by anyone using these files.

The simulation parameters include macroeconomic series (see Tables D1 and D3) and series on age-labor income profiles (see Table D4). We describe them in turn.

The macroeconomic series are directly taken from the national accounts tables reported Appendix A (see formulas in excel files). The only noticeable feature is that in order to run annual level simulations we annualize the decennial-averages macro series of the 18201913 period. We did so by assuming constant growth rates, saving rates and rates of return within each decade (see Table D1). Of course the decennial averages of annualized series do not perfectly coincide with the initial decennial averages. But the gaps due to non linearities are extremely small (see Table D2), and irrelevant for our purposes.

The age-labor income profiles reported on Table D4 should be viewed as approximate. We checked that simulation results are robust with respect to alternative assumptions about these profiles; they are robust. For the recent period, income tax return micro files provide us with very reliable data on age-labor income profiles. We started from the observed tax profile in 2006. In the same way as in the theoretical model (see working paper, section 5), the profiles refer to "augmented labor income", i.e. the sum of net-of-payroll-tax labor income and replacement income (pension income and unemployment benefits). We assumed a constant profile over the 2006-2100 period. Given the observed tax profile appears to be relatively stable during the 1990s-2000s, this seems to be the most reasonable assumption as a first approximation. For the 1820-2006 period we proceeded
as follows (all details are given on the excel file). ${ }^{247}$ We assumed that the profile below age 60 was constant throughout the period. Thanks to our national accounts series, we know the annual 1896-2006 evolution of aggregate replacement income and net-of-payroll-tax labor income. We then used historical estimates on labor force participation rates of individuals aged 60-to-69-year-old in order to allocate aggregate replacement income to the 60-to-69, 70-to-79 and 80-and-ver age groups. ${ }^{248}$

In order to compute the bequest and gift terms entering into transition equation (E.1), we proceeded as follows. We start from the age-level mortality rates coming from our demographic data base: $m_{t}(a)=N_{d t}(a) / N_{t}(a)$. We use the same modelling of differential mortality as that introduced in Appendix B2. That is, we assume that:

$$
\begin{gathered}
m_{t}^{P}(a)=2 \delta_{t}(a) m_{t}(a) /\left(1+\delta_{t}(a)\right) \\
m_{t}^{R}(a)=2 m_{t}(a) /\left(1+\delta_{t}(a)\right) \\
m_{t}^{*}(a)=\operatorname{sh}_{t}^{P}(a) m_{t}^{P}(a)+\left[1-s h_{t}^{P}(a)\right] m_{t}^{R}(a)
\end{gathered}
$$

With: $m_{t}^{P}(a)=$ mortality rate of the poor (bottom 50\%)
$m_{t}{ }^{R}(a)=$ mortality rate of the rich (upper $50 \%$ )
$m_{t}{ }^{*}(a)=$ wealth-weighted average mortality rate

We use the same differential mortality parameters $\delta_{t}(\mathrm{a})$ and $\mathrm{sh}_{\mathrm{t}}{ }^{\mathrm{P}}(\mathrm{a})$ as in Appendix B 2 .

We then compute the predicted aggregate bequest flow $B_{t}{ }^{\top}(a)$ transmitted by individuals of age a at time $t$ by multiplying their aggregate wealth by the wealth-weighted mortality rate:

$$
B_{t}^{\top}(a)=m_{t}^{*}(a) W_{t}(a)
$$

We then compute the aggregate bequest flow transmitted at time $t: B_{t}=\sum_{a \geq 0} B_{t}{ }^{\top}(a)$

[^151]We then compute the aggregate bequest flow $B_{t}{ }^{R}(a)$ received by individuals of age a at time $t$ by multiplying $B_{t}$ by the shares bshare $\mathrm{e}_{\mathrm{t}}(\mathrm{a})$ computed in Appendix C 2 :

$$
B_{t}^{R}(a)=\operatorname{bshare}_{t}(a) B_{t}
$$

We do the same for inter vivos gifts. We take as given the aggregate ratio $\mathrm{v}_{\mathrm{t}}=\mathrm{V}_{\mathrm{t}} / \mathrm{B}_{\mathrm{t}}$ (either we take the observed $v_{t}$, or we run simulations for alternative $v_{t}$ values, see below). We then use the shares donor $_{t}(a)$ and donee ${ }_{t}(a)$ computed in Appendix C 2 in order to compute the aggregate gift flows $\mathrm{V}_{t}{ }^{\top}(\mathrm{a})$ and $\mathrm{V}_{t}{ }^{R}(\mathrm{a})$ transmitted and received by individuals of age a at time t :

$$
\begin{gathered}
V_{t}=V_{t} B_{t} \\
V_{t}^{\top}(a)=\operatorname{donor}_{t}(a) V_{t} \\
V_{t}^{R}(a)=\operatorname{donee}_{t}(a) V_{t}
\end{gathered}
$$

Finally, the gift-corrected aggregate bequest flow is given by: $B_{t}{ }^{*}=B_{t}+V_{t}$.

We have now fully described our dynamic system. Starting from a given age-wealth profile $w_{t}(a)$ at time $t=t_{0}$, we compute the endogenous sequence of aggregate bequest flows $B_{t}{ }^{*}$ for all $t \geq t_{0}$ and age-wealth profiles $w_{t}(a)$ for all $t>t_{0}$, by applying the transition equation (D.1) and the above equations to simulation parameters. We are particularly interested in the endogenous evolution of the inheritance flow-national income ratio $b_{y t}=B_{t}{ }^{*} / Y_{t}$ and of the ratio $\mu_{t}{ }^{*}=b_{y t} / m_{t} \beta_{t}$ (as well as the pre-gift ratio $\mu_{t}=\mu_{t}{ }^{*} /\left(1+v_{t}\right)$ ). The economic forces at play in this dynamic process are exactly the same as those analyzed in the theoretical model with exogenous saving model (see working paper, section 5.2), except that we are now out of steady-state, and except that we take into account all macroeconomic and demographic shocks (on the basis of observed data), as well as inter vivos gifts. ${ }^{249}$

[^152]
## D.2. Simulation results for the 1820-1913 period

Simulation results for the 1820-1913 period are summarized on Table A5. The detailed simulation results, with the endogenous annual dynamics of the age-wealth profile $\mathrm{w}_{\mathrm{t}}(a)$, are reported on separate tables (one for each scenario).

The main findings from these simulations are discussed in the working paper (section 6). Here we discuss additional technical details. First, in all variants, we approximately reproduce the relative stability of $b_{y t}$ around $20 \%$ of national income during the 1820-1913 period. This simply shows that the $19^{\text {th }}$ century was close to a steady-state, and that with low growth rates and high rates of return, the steady-state inheritance flow tends to be close to $20 \%$ irrespective of the specific saving behaviour. The key assumption here is the flatness of the age-saving rates of profile: with dissaving at old age, one would never be able to reproduce such levels of inheritance flows.

Next, if one wants to obtain a better fit for the byt pattern, and most importantly if one wants to be also able to reproduce the full observed age-wealth profile $\mathrm{w}_{\mathrm{t}}(\mathrm{a})$, then one needs to assume class saving. The observed age-wealth profile at the end of the period is steeply rising at old age: around 1900-1910, individuals aged 70-to-79 and 80-and-over own as much as 180\%-200\% of the average wealth owned by the 50-to-59-year-old (see Appendix B, Table B5). By comparing with the simulated age-wealth profiles under scenario a1-a3 and b1-b3, one can see that the only way to get close to this is to assume that savings entirely come from capital income. With uniform saving, and even more so with reverse class saving, the simulated profile is far too flat, and the resulting pattern of $b_{y t}$ and $\mu_{t}$ ratios is somewhat too low.

In fact, in order to fully reproduce the steepness of the age-wealth profile and the very high levels of $b_{y t}$ around 1900-1910, one would need to assume not only that (most) savings come from capital income, but also that the average saving rate $\mathrm{s}_{\mathrm{K}}(\mathrm{a})$ actually rises with age. This would be consistent with a simple consumption satiation effect among elderly wealth holders. This interpretation is also consistent with the fact that the age-wealth profile in Paris (where top wealth levels were particularly high) was in 1900-1910 even more steeply rising than in the rest of France: the average wealth of the 70-to-79 and 80-
and-over age groups was as large as $300 \%$ of that of the 50-to-59 age group, which cannot be accounted for without a steeply rising $\mathrm{s}_{\mathrm{K}}(\mathrm{a})$ profile. ${ }^{250}$

Finally, we are particularly interested in the simulation results under the zero gift assumption. In scenario a1-a3, we take as given the observed gift-bequest ratio $\mathrm{v}_{\mathrm{t}}$. This generates bizarre predictions on the age-wealth profiles at mid-19 ${ }^{\text {th }}$ century. For instance, the 50-to-59 age group appears to be unplausibly poor. This seems to be due to the fact that gifts are very important at that time ( $\mathrm{v}_{\mathrm{t}}$ is about $40 \%$ in the 1840s, and then gradually falls to about $20 \%$ in the 1860s-1870s), and that we probably attribute an excessive fraction of these gifts to donors in their 50s (our estimates on the age structure of donors and donees are highly approximate for the $19^{\text {th }}$ century). So in order to abstract entirely from the issue of inter vivos gifts (which raise interesting and complex issues on their own right), we assume in scenario b1-b3 that there was no gift at all throughout the 1820-1913 period ( $\mathrm{v}_{\mathrm{t}}=0 \%$ ). Of course this implies that we significantly underestimate the aggregate bequest flow at the beginning of the period (since by assumption we miss the gift part). But this clarifies considerably the dynamics of the age-wealth profile, and confirms that one needs to assume class saving in order to reproduce observed profiles.

Most importantly, by the end of the period (around 1900-1910, and in fact as early as the 1850s-1860s), we generate as much total bequests under the zero gift assumption than with the observed gift ratio (compare scenario b1-b3 with a1-a3). In other words, if wealth holders stop making gifts and hold on to their wealth until their death, then their wealth at death will be higher, and total wealth transmission will eventually be approximately the same as what it would have been in the presence of gifts. This finding justifies the fact that as a first approximation we chose to simply add up cross sectional gifts and bequests in order to compute the total flow of wealth transmission.

## D.3. Simulation results for the 1900-2100 period

Simulation results for the 1900-2100 period are summarized on Table A6. The detailed simulation results, with the endogenous annual dynamics of the age-wealth profile $\mathrm{w}_{\mathrm{t}}(a)$, are reported on separate tables (one for each scenario).

[^153]The main findings from these simulations are discussed in the working paper (section 6). Here we give additional technical details. First, by comparing the results obtained under scenario a1-a3, one can see that the fact that pensions and replacement rates were relatively low at mid $20^{\text {th }}$ century does contribute to make inheritance flows smaller, but that this is a relatively small effect. This is consistent with the theoretical results obtained in the exogenous saving model.

Next, by comparing scenario a1 with scenario b1-b2, one can see that class saving is no longer adequate to account for $20^{\text {th }}$ century patterns. Uniform saving offers a better fit. As far as reproducing the 1950s nadir is concerned, reverse class saving offers an even better fit. In order to fully reproduce the extremely low inheritance flow observed in the 1950s (about 4\% of national income), one would actually need to assume non-age-neutral war-induced capital shocks (i.e. the elderly might have suffered from more than proportional shocks, e.g. because they held a larger fraction of their wealth in public bonds or other nominal assets), and/or negative saving from wealth holders (e.g. because a number of rentiers did not adjust downwards their living standards sufficiently fast following the fall in asset values and returns), and/or negative saving from the elderly in general (because of particularly low pensions around that time). In order to settle the issue, one would need to explicitly introduce distributional considerations into the analysis and to use micro level data, which we plan to do in future research.

Maybe the most interesting simulations are scenario c1 (where we freeze the gift parameter $\mathrm{v}_{\mathrm{t}}$ at its 1980 level for the 1980-2100 period) and scenario c2 (where we set $\mathrm{v}_{\mathrm{t}}=0 \%$ throughout the 1900-2100 period). The key finding is we still reproduce observed patterns relatively well. This shows that the large rise in gifts which occurred since the 1980s is not driving the recent rise in measured inheritance flows. In particular, by looking at the predicted age-wealth profiles, one can see that if gifts had not risen since 1980 (or if they had been absent throughout the period) then the age-wealth profile would have been substantially more steeply rising at old age by 2000-2010, thereby generating large extra wealth transmission at death, thereby compensating the absence of a larger gift flow. Note however that the compensation is not complete (i.e. long run levels of $b_{y}{ }^{*}$ are somewhat smaller in the small-gift or zero-gift scenarios c1-c2), which suggests that there was a little bit of overshooting in the rise of gifts since the 1980s (possibly due to tax incentives), and that a (small) fraction of the observed gift level is not sustainable.

Regarding the 2010-2100 period, we explored several scenarios corresponding to various assumptions about future growth rates g , net-of-tax rates of returns (1-т)r, and saving rates s (which might or might not react to changes in g and (1-T)r). Variants a1-c3 correspond to our baseline scenario: $\mathrm{g}=1.7 \%$ (average 1979-2009 growth rate), (1-T)r=3.0\% (capital share fixed at 2008 level), and s=9.4\% (average 1979-2009 saving rate). In variants d1-e4 we explore the consequences of growth slowdown ( $\mathrm{g}=1.0 \%$ ) and/or rise in the net-of-tax rate of return ((1-т)r=5.0\%). In variants $\mathrm{f} 1-\mathrm{g} 4$ we explore the consequences of rise in the growth rate ( $\mathrm{g}=5.0 \%$ ), possibly accompanied by a rise in the net-of-tax rate of return. The main findings are discussed in the working paper. Here we mention two additional points.

First, it is equivalent in the model whether the rise in the net-of-tax rate of return comes from a rise in the capital share or from a decline in the capital tax rate. This is because we assume in all variants that the overall tax rate remains constant after 2010 (i.e. the disposable income-national income ratio is supposed to be fixed), so in effect any capital tax cut must be compensated by a corresponding rise in labor taxes.

Next, if saving rates do not adjust in our model, then changes in the growth rate will have large long run impact on the wealth-income ratio $\beta^{*}=s / g$. In the baseline scenario, with $g=1.7 \%$ and $s=9.4 \%$, the long run $\beta^{*}$ is about $560 \%$, i.e. approximately the same level as in 2008-2009. In other scenarios, we consider variants where the saving rates adjust so as to keep the long-run wealth-income ratio approximately constant around 500\%-600\%. This allows us to disentangle the impact of $g$ on $b_{y}$ going through changes in $\beta$ from the impact of $g$ on $b_{y}$ going through changes in $\mu$.

For instance, a substantial part of the rise of $b_{y}$ to $22 \%-23 \%$ in scenarios $d 1-d 2$ is due to the fact that the growth slowdown leads to a rise in the wealth-income ratio to about 650\% by 2050 and $750 \%$ by 2100 (about two thirds of the rise comes from this channel). This is a plausible outcome. But in order to separate the various effects, we also consider in scenarios d3-d4 the possibility that the saving rate adjusts downwards to $6 \%$, so that the wealth-income ratio remains stable at $550 \%-600 \%$. The rise of $b_{y}$ is then limited to $17 \%-$ $18 \%$ in 2100 . By comparing scenario a1 with scenarios d3-d4, one can also compute the relative impacts of $g$ and $r$ on steady-state $\mu^{*}$. E.g. in the baseline scenario $a 1, b_{y}=16.0 \%$ in 2050. In scenario $d 3, b_{y}=16.9 \%$; in scenario $d 4, b_{y}=17.3 \%$. That is, the growth slowdown appears to explain about two thirds of the total rise of $\mu^{*}$ by 2050 , while the rise in the rate
of return explains about one third. This is consistent with the theoretical results obtained with the exogenous saving model: the $r$ effect is multiplied $s_{k}$, and is therefore smaller than the $g$ effect. Note however that other saving specifications would deliver different results. E.g. in the wealth-in-the-utility-function models, where individuals save a fixed fraction of their lifetime resources, changes in $g$ and $r$ have the same quantitative impact (only the difference r-g matters). This should be more closely investigated in future research.

## D.4. Estimation and simulation results on lifetime resources by cohort

We use the simulated model in order to compute lifetime resources by cohort $\tilde{\mathrm{y}}^{\mathrm{x}}=\tilde{\mathrm{b}}^{\mathrm{x}}+\tilde{\mathrm{y}}_{\mathrm{L}}{ }^{\mathrm{x}}$, for all cohorts born between 1800 and 2030. The main findings from these computations are discussed in the working paper (sections 7.1-7.2). Here we present the full results (see Table D7-D8) and provide technical details (see the do-file dolifetimecohorts18002000.txt for the corresponding computer code).

For all cohorts $x \in[1800,2030]$, we compute the aggregate value of inherited resources and labor incomes resources received during the entire lifetime of cohort x (i.e. between age $a=0$ and age $a=100$ ), capitalized at age 50:

$$
\begin{align*}
& \widetilde{B}^{x}=\sum_{x \leq t \leq x+100}\left(1+r_{t s}\right)\left(B_{t}^{x}+V_{t}^{x}\right) \\
& \widetilde{Y}_{L}^{x}=\sum_{x \leq t \leq x+100}\left(1+r_{t s}\right) Y_{t}^{x} \tag{D.3}
\end{align*}
$$

With: $B_{t}{ }^{x}=$ aggregate value of bequest flows received at time $t$ by cohort $x$ $V_{t}{ }^{x}=$ aggregate value of inter vivos gift flows received at time $t$ by cohort $x$ $Y_{t}{ }^{x}=$ aggregate value of labor income flows received at time $t$ by cohort $x$ $1+r_{t s}=$ cumulated rate of return between year $t$ and year $s=x+50$

We then compute average values $\widetilde{\mathrm{b}}^{\mathrm{x}}=\widetilde{\mathrm{B}}^{\mathrm{x}} / \mathrm{N}^{\mathrm{x}}$ and $\widetilde{\mathrm{y}}_{\mathrm{L}}{ }^{\mathrm{x}}=\widetilde{\mathrm{Y}}_{\mathrm{L}}{ }^{\mathrm{x}} / \mathrm{N}^{\mathrm{x}}$ by dividing aggregate values by cohort size $\mathrm{N}^{\mathrm{x}}$ (we use cohort size at birth). The corresponding values, expressed in 2009 euros, are reported on Table D7 (benchmark scenario) and Tables D8 (low-growth, high-return scenario). ${ }^{251}$ We also report the inheritance share in total lifetime resources

[^154]$\hat{\mathrm{a}}^{\mathrm{x}}=\tilde{\mathrm{b}}^{\mathrm{x}} /\left(\tilde{\mathrm{b}}^{\mathrm{x}}+\tilde{\mathrm{y}}_{\mathrm{L}}{ }^{\mathrm{x}}\right)$ and the inheritance-labor ratio $\psi^{\mathrm{x}}=\tilde{\mathrm{b}}^{\mathrm{x}} / \tilde{\mathrm{y}}_{\mathrm{L}}{ }^{\mathrm{x}}$, as well as the capitalization factors $\lambda_{B}{ }^{x}$ and $\lambda_{L}{ }^{x}$ (i.e. the ratios between capitalized lifetime resources and the uncapitalized resources obtained by replacing $1+r_{\text {ts }}$ by 1 in equations (D.2)-(D.3)), and the ratio $\lambda^{x}=\lambda_{L}{ }^{\mathrm{x}} / \lambda_{B}{ }^{x}$. For $19^{\text {th }}$ century cohorts, age 50 happens relatively late in life, so the capitalization factors $\lambda_{B}{ }^{x}$ and $\lambda_{L}{ }^{x}$ are far above $100 \%$. For $20^{\text {th }}$ century cohorts, age 50 is closer to mid life, so the capitalization factors are closer to $100 \%$. In both cases, the ratio $\lambda^{x}=\lambda_{L}{ }^{x} / \lambda_{B}{ }^{x}$ is always relatively close to $100 \%$. ${ }^{252}$ Of course the choice of age $a=50$ has no consequence on the ratios $\hat{\alpha}^{x}, \Psi^{x}$ and $\lambda^{x}$, since we use the same rates of return for inheritance and labor ressources. ${ }^{253}$

We also report on Tables D7-D8 the values for the two-dimensional inequality indicators discussed in the working paper (section 7.2). These were computed by applying directly the ratio $\psi^{x}$ to the intra-cohort distributions of inherited wealth and labor income indicated in the working paper (Table 4). ${ }^{254}$ In order to compute $\varepsilon^{\mathrm{x}}$ (i.e. the proportion of cohort x with inheritance ressources larger than bottom 50\% labor resources), we assume that the fraction fraction $\mathrm{p}^{\mathrm{x}}(\mathrm{b})$ of cohort x with inheritance resources larger than b can be approximated by a simple type-1 Pareto distribution, and we borrow Pareto coefficients from our previous work on wealth concentration. ${ }^{255}$

[^155]
## D.5. Estimation and simulation results on inheritance shares in wealth accumulation

We also use the simulated model in order to compute the non-capitalized and capitalized inheritance shares in aggregate wealth $\varphi_{t}{ }^{M}$ and $\varphi_{t}{ }^{\text {KS }}$ for all years between 1850 and 2100. The main findings from these computations are discussed in the working paper (section 7.3). Here we present the full results (see Table D9-D10) and provide technical details (see the do-file doinheritanceshare18502100.txt for the corresponding computer code).

For all years $t \in[1850,2100]$, we compute $\varphi_{t}{ }^{M}$ and $\varphi_{t}{ }^{K S}$ by dividing the cumulated value of past bequests and gifts $\hat{B}_{t}$ and $\widetilde{B}_{t}$ by aggregate wealth $W_{t}$ :

$$
\begin{gather*}
\varphi_{t}{ }^{M}=\hat{B}_{t} / W_{t}, \text { with: } \hat{B}_{t}=\sum_{t-100 \leq s s t}\left(B_{s t}+V_{s t}\right)  \tag{D.4}\\
\varphi_{t}{ }^{k s}=\widetilde{B}_{t} / W_{t}, \text { with: } \tilde{B}_{t}=\sum_{t-100 \leq s s t}\left(1+r_{s t}\right)\left(B_{s t}+V_{s t}\right) \tag{D.5}
\end{gather*}
$$

With: $\mathrm{B}_{\mathrm{st}}=$ aggregate bequests received at time s by individuals who are still alive at time t
$V_{s t}=$ aggregate gifts received at time $s$ by individuals who are still alive at time $t$
$1+r_{s t}=$ cumulated rate return between year $s$ and year $t$

In order to compute $\mathrm{B}_{\text {st }}$ and $\mathrm{V}_{\text {st }}$, we need to know which fraction of the various cohorts is still alive at in year t , so we computed survival rates using the same differential mortality parameters as in the general simulations (see do-file). The corresponding wealth aggregates, expressed in 2009 billions euros, are reported on Table D7 (benchmark scenario) and Tables D8 (low-growth, high-return scenario). We actually report three series $\hat{B}_{t 0}, \hat{B}_{t}$ and $\widetilde{B}_{t}$ for cumulated inherited wealth, as well as the three corresponding series $\varphi_{t 0}{ }^{M}, \varphi_{t}{ }^{\mathrm{M}}$ and $\varphi_{t}{ }^{\mathrm{KS}}$ for shares in aggregate wealth. The raw series $\hat{B}_{t 0}$ correspond to nominal inherited wealth and are reported only for illustrative purposes: we did not even adjust past bequest and gifts flows $B_{s t}$ and $V_{s t}$ for price inflation, so of course the corresponding wealth shares $\varphi_{t 0}{ }^{M}$ are artificially low, especially following periods of rapid inflation (e.g. $\varphi_{t 0}{ }^{M}$ is less than $10 \%$ around 1950). The uncapitalized series $\hat{B}_{t}$ were

[^156]computed by adjusting past bequest and gifts flows $B_{s t}$ and $V_{\text {st }}$ by cumulated consumer and asset price inflation $1+p_{s t}$ and $1+q_{s t}$ between year $s$ and year $t$. This seems to be the most reasonable way to define uncapitalized inherited wealth $\hat{B}_{t}$, and the corresponding uncapitalized inheritance wealth share in aggregate wealth $\varphi_{t}{ }^{M} \cdot{ }^{256}$ In the capitalized series $\widetilde{B}_{t}$ and $\varphi_{t}{ }^{\text {Ks }}$, we also apply to past bequest and gift flows the cumulated rate of return $1+r_{s t}$, as indicated by equation (D.5).

We also report on Tables D7-D8 the average capitalization factor, i.e. the ratio $\widetilde{B}_{t} / \hat{B}_{t}$. Note that with the deterministic demographic structure used in the stylized model, everybody inherits at age $a=I$, so the capitalization factor only depends on $r, g$ and generation length H , and is given by simple steady-state formulas. ${ }^{257}$ However here we use the observed demographic structure of bequests and gifts, with full demographic shocks, i.e. individuals receive bequests and gifts at all ages. So for instance in each cohort there is a fraction of individuals who inherited very early in life (much before age I, e.g. because their parents died early), and a fraction of individuals who inherited very late (or even died before their parents). Because capitalized returns are a convex function of time, this tends to push upwards the average capitalization factor $\widetilde{\mathrm{B}}_{\mathrm{t}} / \hat{\mathrm{B}}_{\mathrm{t}}$, i.e. the few individuals in each cohort who inherited very early in life have an enormous capitalized inherited wealth and can have a substantial impact on aggregate capitalized inherited wealth. In effect, non-deterministic demography makes the capitalized definition $\varphi_{t}^{\text {KS }}$ even more sensitive to $r$-g than it naturally is. We see no obvious reason why we should exclude or truncate early successors, however, so the series reported on Table D7-D8 do not make any such truncature. For illustrative purposes, we indicate the shares of noncapitalized and capitalized inherited wealth which were received more than 30 years or 50 years before the current year. So for instance, as of 2010, bequests and gifts received before 1980 represent $13 \%$ of non-capitalized inherited wealth $\hat{B}_{t}$ and $39 \%$ of capitalized inherited wealth $\widetilde{B}_{t}$; those received before 1960 represent $2 \%$ of non-capitalized inherited

[^157][^158]wealth $\hat{B}_{t}$ and $15 \%$ of capitalized inherited wealth $\widetilde{B}_{t}$ (see Table D9). As compared to the steady-state formulas, there are other effects going in the opposite direction: we take into account all observed bequests and gifts, so for instance this includes bequests and gifts to surviving spouses and/or siblings, which often occur not very long before the receiver's death (and typically less than $\mathrm{H}=30$ years before the receiver's death, so that average capitalization length is effectively less than 30). Overall, the average capitalization factor $\widetilde{B}_{t} / \hat{B}_{t}$ is relatively close to the theoretical steady-state level in the benchmark scenario (it is actually a bit lower), and it is significantly higher in the low-growth, high-return scenario (reflecting the strength of the convexity effect). ${ }^{258}$

## D.6. List of Stata format data files and do-files

simulationparameters18201913.dta: data file containing the parameters used for the 18201913 simulations (see Tables D1 and D4)
simulationparameters19002100.dta: data file containing the parameters used for the 19002100 simulations (see Tables D3 and D4)
dosimul18201913.txt: do-file generating 1820-1913 simulation results
dosimul19002100.txt: do-file generating 1900-2100 simulation results
simulresults18201913.dta, simulresults19002100.dta, simulwealth18201913.dta, simulwealth19002100.dta, simulwealth19002100(scenariod2), simulwealth18202100.dta: data files containing 1820-1913 and 1900-2100 simulation results
dolifetimecohorts18002000.txt: do-file generating lifetime resources by cohort
lifetime18002000.dta: data file containing the results on lifetime resources by cohort

[^159]doinheritanceshare18502100.txt: do-file generating capitalized and non-capitalized inheritance shares in aggregate wealth accumulation
inheritanceshares18502100.dta: data file containing the results on inheritance shares

## Appendix E: Steady-state inheritance formulas

In the working paper we develop a stylized model of wealth accumulation, inheritance and growth, and present a number of theoretical results and steady-state formulas on inheritance flows (see section 5). Omitted proofs for these results and formulas are provided here, together with a number of tables and figures illustrating how the various steady-state formulas can be used with real numbers (sections E1-E5). We then show how the main theoretical results and formulas can be extended to more general demographic structures, and in particular to the case with population growth (section E6).

## E.1. Proof of Proposition 3 (section 5.2)

(exogenous savings model, closed economy)

With exogenous saving rates $s_{L} \geq 0 \& s_{k} \geq 0$, the steady-state wealth-income ratio $\beta_{t}=w_{t} / y_{t}$ is equal to $\beta^{*}=s / g$ and the steady-state rate of return $r_{t}$ is equal to $r^{*}=\alpha / \beta$ (see Proposition 1). We are looking for the steady-state ratio $\mu_{t}=b_{t} / w_{t}=w_{t}(D) / w_{t}$.
(i) Case $\rho=1$. First consider the case $\rho=1$ (i.e. $100 \%$ replacement rate). Because savings are assumed to be linear, the average wealth $w_{t}(a)$ of a-year-olds at time $t$ can be broken down into two components, i.e. an inherited wealth component $w_{B t}(a)$, and a labor wealth component $w_{\text {Lt }}(a)$ :
If $a \in\left[A, I\left[\quad w_{t}(a)=w_{L t}(a)=\int_{t+A-a \leq s s t} S_{L} y_{L s} e^{s_{k} r^{*}(t-s)} d s\right.\right.$
If $a \in[I, D] \quad w_{t}(a)=w_{B t}(a)+w_{L t}(a)=b_{t+1-a} e^{s_{K} r^{*}(a-1)}+\int_{t+A-a \leq s s t} S_{L} y_{L s} e^{s_{k} r^{*}(t-s)} d s$
Since $y_{L t}$ and $b_{t}$ grow at rate $g$ in steady-state, we have: $y_{L s}=y_{L t} e^{-g(t-s)}$ and $b_{t+1-a}=b_{t} e^{-g(a-1)}$. Therefore we have:
If $a \in\left[A, I\left[\quad w_{t}(a)=w_{L t}(a)=s_{L} y_{L t}\left[1-e^{-\left(g-s_{k} r^{*}\right)(a-A)}\right] /\left(g-s_{K} r^{*}\right)\right.\right.$
If $a \in[I, D] \quad w_{t}(a)=w_{B t}(a)+w_{L t}(a)=b_{t} e^{-\left(g-s_{K} r^{*}\right)(a-1)}+s_{L} y_{L t}\left[1-e^{-\left(g-s_{K} r^{*}\right)(a-A)}\right] /\left(g-s_{K} r^{*}\right)$
Since $g-s_{K} r^{*}=\left(s-\alpha s_{K}\right) / \beta=(1-\alpha) s_{L} / \beta$, one can replace $s_{L} y_{L I} /\left(g-s_{K} r^{*}\right)$ by $w_{t}$ and obtain:
If $a \in\left[A, I\left[\quad w_{t}(a)=w_{L t}(a)=\left[1-e^{-\left(g-s_{k} r^{*}\right)(a-A)}\right] w_{t}\right.\right.$
If $a \in[I, D] \quad w_{t}(a)=w_{B t}(a)+w_{L t}(a)=b_{t} e^{-\left(g-s_{k} r^{*}\right)(a-I)}+\left[1-e^{-\left(g-s_{k} r^{*}\right)(a-A)}\right] w_{t}$
It follows that the steady-state ratio $\mu_{t}=b_{t} / w_{t}=w_{t}(D) / w_{t}$ is given by:

$$
\begin{equation*}
\mu^{*}=\mu(\mathrm{g})=\frac{1-\mathrm{e}^{-\left(\mathrm{g}-\mathrm{sk} r^{*}\right)(\mathrm{D}-\mathrm{A})}}{1-\mathrm{e}^{-\left(\mathrm{g}-\mathrm{skr} r^{2}\right) H}} \tag{E.1}
\end{equation*}
$$

Alternatively, instead of assuming that $\mu_{\mathrm{t}}=\mathrm{b}_{\mathrm{t}} / \mathrm{w}_{\mathrm{t}}$ is in steady-state, we can write the transition equation for $\mu_{\mathrm{t}}$ as a function of the $\mu_{\mathrm{t}-\mathrm{H}}$ of the previous generation: ${ }^{259}$

$$
\mu_{t}=\mu_{t-H} e^{-\left(g-S_{k} r^{\star}\right) H}+\left[1-e^{-\left(g-s_{k} r^{*}\right)(D-A)}\right]
$$

As long as $s_{L}>0, g-s_{k} r^{*}>0$, so this dynamic process converges: $\mu_{t} \rightarrow \mu^{*}=\mu(g)$ as $t \rightarrow+\infty$. Since $g-s_{K} r^{*}=g(1-\alpha) s_{L} / s$, formula (E.1) can also be rewritten as follows:

$$
\begin{equation*}
\mu^{*}=\mu(\mathrm{g})=\frac{1-\mathrm{e}^{-\frac{(1-\alpha))_{\mathrm{L}}}{\mathrm{~s}} \mathrm{~g}(\mathrm{D}-\mathrm{A})}}{1-\mathrm{e}^{-\frac{(1-\alpha) \mathrm{S}_{\mathrm{L}}}{\mathrm{~s}} \mathrm{gH}}} \tag{E.2}
\end{equation*}
$$

Note that as $\mathrm{s}_{\mathrm{L}} \rightarrow 0, \mu(\mathrm{~g}) \rightarrow \bar{\mu}=(\mathrm{D}-\mathrm{A}) / \mathrm{H}$ : we are back to the class savings case.
$\bullet \mathrm{s}_{\mathrm{L}}>0, \mu^{\prime}(\mathrm{g})<0$, with $\mu(\mathrm{g}) \rightarrow \bar{\mu}$ as $\mathrm{g} \rightarrow 0$ and $\mu(\mathrm{g}) \rightarrow 1$ as $\mathrm{g} \rightarrow+\infty$.
Note also that for given g , a rise in (1- $\alpha$ ) $\mathrm{s}_{\mathrm{L}} / \mathrm{s}$ (the share of total savings coming from labor income) has the same impact on steady-state $\mu^{*}$ as a rise in $g$ (and conversely for a rise in the share of total savings coming from capital income $\left.\alpha_{s_{k}} / s\right)$.
In the uniform savings case ( $\mathrm{s}_{\mathrm{L}}=\mathrm{s}_{\mathrm{K}}=\mathrm{s}$ ), $\mathrm{g}-\mathrm{s}_{\mathrm{K}} \mathrm{r}^{*}=(1-\alpha) \mathrm{g}$, so we have:

$$
\begin{equation*}
\mu^{\star}=\mu(\mathrm{g})=\frac{1-\mathrm{e}^{-(1-\alpha) g(D-A)}}{1-\mathrm{e}^{-(1-\alpha) g H}} \tag{E.3}
\end{equation*}
$$

For illustrative purposes, numerical examples of age-wealth profiles for bequest wealth $w_{B t}(a) / w_{t}$ and labor wealth $w_{L t}(a) / w_{t}$ are represented on Figures E1-E2. ${ }^{260}$ Because g$S_{K} r^{*}>0$, i.e. the growth effect dominates the savings effect, bequest wealth $w_{B t}(a) / w_{t}(a)$ declines with age a (above inheritance age). Labor wealth $w_{L t}(a) / w_{t}(a)$ naturally rises with age. By definition, the total wealth profile $w_{t}(a) / w_{t}$ is the sum of the two profiles: it is rising until age $\mathrm{a}=\mathrm{I}$ and then declining (see Figure E3). I.e. the cross-sectional wealth profile is hump-shaped (this is because of the growth effect), in spite of the fact that longitudinal profiles are always upward sloping in the exogenous saving model (there is no old-age dissaving). ${ }^{261}$ As $\mathrm{g} \rightarrow 0$, both profiles become almost flat and the relative importance of

[^160]labor wealth declines; so that in the limit the total age-wealth profile looks like the profile prevailing in the class saving case (see working paper, Figure 12), and $\mu^{*} \rightarrow \bar{\mu}$. Conversely, as $g \rightarrow+\infty$, the bequest wealth profile becomes more and more downward sloping, and the labor wealth profile more and more upward sloping; so that in the limit the total wealth profiles displays two peaks at ages I and D, and $\mu^{*} \rightarrow 1$.
(ii) Case $\rho<1$. Now consider the case $\rho \leq 1$ (less than $100 \%$ replacement rates). Labor wealth $W_{L t}(a)$ of retired individuals $(a \in[R, D])$ is now given by:
$w_{L t}(a)=\frac{D-A}{(R-A)+\rho(D-R)}\left[\int_{t+A-a \leq s s t+R-a} s_{L} y_{L s} e^{s_{k} r^{*}(t-s)} d s+\int_{t+R-a \leq s s t} s_{L} \rho y_{L s} e^{s_{k} r^{*}(t-s)} d s\right]$
That is:
$W_{L t}(a)=\frac{D-A}{(R-A)+\rho(D-R)} w_{t}\left[\left[e^{-\left(g-s_{k} r^{*}\right)(a-R)}-e^{-\left(g-s_{k} r^{*}\right)(a-A)}\right]+\rho\left[1-e^{-\left(g-s_{k} r^{*}\right)(a-R)}\right]\right]$

And the steady-state ratio $\mu_{\mathrm{t}}=\mathrm{b}_{\mathrm{t}} / \mathrm{w}_{\mathrm{t}}=\mathrm{w}_{\mathrm{t}}(\mathrm{D}) / \mathrm{w}_{\mathrm{t}}$ is given by:

$$
\begin{equation*}
\mu^{*}=\mu(g, \rho)=\frac{D-A}{(R-A)+\rho(D-R)} \frac{e^{-\left(g-s_{K^{*}}\right)(D-R)}-e^{-\left(g-s_{K^{*}} \kappa^{*}\right)(D-A)}+\rho\left(1-e^{-\left(g-s_{K^{*}}{ }^{*}\right)(D-R)}\right)}{1-e^{-\left(g-s_{K^{*}}\right) H}} \tag{E.4}
\end{equation*}
$$

With $\rho=1$, we are back to the above formula. With $\rho<1, \mu(\mathrm{~g}, \rho) \rightarrow \bar{\mu}$ as $\mathrm{g} \rightarrow 0$.
Note also that $\mu(\mathrm{g}, \rho) \rightarrow \mu_{0}(\rho)<1$ as $g \rightarrow+\infty$, with $\mu_{0}(\rho)$ given by:

$$
\mu_{0}(\rho)=\frac{\rho(D-A)}{(R-A)+\rho(D-R)}
$$

$\mu_{0}{ }^{\prime}(\rho)>0 . \mu_{0}(\rho) \rightarrow 1$ as $\rho \rightarrow 1 . \mu_{0}(\rho) \rightarrow 0$ as $\rho \rightarrow 0$.

The key difference with the case $\rho=1$ is that retired individuals now do not fully benefit from labor income growth, so for $\rho$ small and $g$ high the labor wealth profile $w_{\mathrm{Lt}}(a) / w_{t}$ becomes downward sloping above retirement age. In the extreme case $\rho=0$ and $g \rightarrow+\infty$, the relative

[^161]wealth of the elderly $\mu^{*}$ tends toward $0 \%$ (they become infinitely poor as compared to workers), and inheritance vanishes. But for this effect to be quantitatively significant, growth rates need to be enormous. E.g. for $\rho=0 \%$ and $g=10 \%$, then $\mu^{*}=40 \%$ and $b_{y}{ }^{*}=4 \%$. For more reasonable values of $g, \mu^{*}$ and $b_{y}{ }^{*}$ are much closer to class saving levels. On Table E1 we provide numerical illustrations of the $\mu(\mathrm{g})$ and $\mu(\mathrm{g}, \mathrm{\rho})$ formulas for various parameter values. ${ }^{262}$

## E.2. Proof of Proposition 4 (section 5.2)

(exogenous savings model, open economy)
(i). Wealth-income ratio. We first solve for the long-run $\beta_{t}=W_{t} / Y_{t}$. In the closed economy case, steady-state $\beta^{*}=s / g$ and $r^{*}=\alpha g / s$ (with $s=(1-\alpha) s_{L}+\alpha s_{k}$ ) follow directly from the wealth accumulation equation $d W_{t} / d t=s Y_{t}$, i.e. $d \beta_{t} / d t=s-g \beta_{t}$. The open economy case introduces two complications into this equation: the capital share (incl. net foreign asset income) generally differs from $\alpha$, so the aggregate saving rate is now endogenous (except in the uniform saving case $\mathrm{s}=\mathrm{s}_{\mathrm{L}}=\mathrm{s}_{\mathrm{K}}$ ); the long run growth rate of national income can differ from g , in case the world rate of return r is larger than $\overline{\mathscr{D}}=\mathrm{g} / \mathrm{s}_{\mathrm{K}}$ (in which case it will be equal to $\left.\mathrm{s}_{\mathrm{K}} \overline{\mathscr{D}}>\mathrm{g}\right)$. To solve the model, we use the following notations. Private wealth $W_{t}$ is now equal to the sum of the domestic capital stock $\mathrm{K}_{\mathrm{t}}$ and net foreign assets $\mathrm{W}_{\mathrm{Ft}}(\geq 0$ or $\leq 0)$ : $\mathrm{W}_{\mathrm{t}}=\mathrm{K}_{\mathrm{t}}+\mathrm{W}_{\mathrm{Ft}}$. National income $\mathrm{Y}_{\mathrm{t}}$ is equal to the sum of domestic income (domestic output, i.e. net domestic product) $\mathrm{Y}_{\mathrm{pt}}=\mathrm{F}\left(\mathrm{K}_{\mathrm{t}}, \mathrm{H}_{\mathrm{t}}\right)$ and net foreign asset income rW Ft : $Y_{t}=Y_{p t}+r W_{F t}=\left(1+r \beta_{\mathrm{Ft}}\right) Y_{\mathrm{pt}}$ (with $\beta_{\mathrm{Ft}}=W_{\mathrm{Ft}} / Y_{\mathrm{pt}}=$ foreign wealth-domestic income ratio). We maintain the Cobb-Douglas assumption for domestic production $\left(Y_{p t}=F\left(K_{t}, H_{t}\right)=K_{t}^{\alpha} H_{t}{ }^{1-\alpha}\right)$, so the domestic capital/output ratio $\beta_{\mathrm{Kt}}=\mathrm{K}_{\mathrm{t}} / Y_{\mathrm{pt}}$ is permanently equal to $\beta_{\mathrm{K}}{ }^{*}=\alpha / \mathrm{r}$, and the growth rate of domestic output is permanently equal to g . The wealth-national income ratio $\beta_{\mathrm{t}}=\mathrm{W}_{\mathrm{t}} / Y_{\mathrm{t}}$ is equal to $\beta_{\mathrm{pt}} /\left(1+\mathrm{r} \beta_{\mathrm{Ft}}\right)$, where $\beta_{\mathrm{pt}}=\mathrm{W}_{\mathrm{t}} / \mathrm{Y}_{\mathrm{pt}}=\beta_{\mathrm{kt}}+\beta_{\mathrm{Ft}}$ is the wealth-domestic income ratio. The wealth accumulation equation can be written as follows:

$$
\begin{gathered}
d W_{t} / d t=d W_{F t} / d t+d K_{t} / d t=s_{L} Y_{L t}+s_{K} Y_{K t} \\
\text { With: } Y_{L t}=(1-\alpha) Y_{p t}=\text { labor income } \\
Y_{K t}=r W_{t}=\alpha Y_{p t}+r W_{F t}=\text { corrected capital income (incl. net foreign asset income) }
\end{gathered}
$$

[^162]Note that $\mathrm{dK}_{\mathrm{t}} / \mathrm{dt}=\mathrm{gK} \mathrm{K}_{\mathrm{t}}=\mathrm{gaY} \mathrm{ppt} / \mathrm{r}$.
By differentiating $\beta_{\mathrm{Ft}}=\mathrm{W}_{\mathrm{Ft}} / Y_{\mathrm{pt}}$ one then obtains the following dynamic equation:

$$
d \beta_{\mathrm{Ft}} / \mathrm{dt}=(1-\alpha) \mathrm{s}_{\mathrm{L}}+\left(\alpha+r \beta_{\mathrm{Ft}}\right) \mathrm{s}_{\mathrm{K}}-\mathrm{ga} / \mathrm{r}-\mathrm{g} \beta_{\mathrm{Ft}}=(\mathrm{s}-\mathrm{g} \alpha / r)-\left(\mathrm{g}-\mathrm{s}_{\mathrm{K}} \mathrm{r}\right) \beta_{\mathrm{Ft}}
$$

Where $s=(1-\alpha) s_{L}+\alpha s_{K}$ is again the aggregate closed economy saving rate.
If $r>\bar{r}=g / s_{k} t$, i.e. if the rate of wealth reproduction $s_{k} r$ is larger than $g$, then this dynamic equation admits no (stable) steady-state: $\beta_{\mathrm{Ft} \rightarrow+\infty}$ as $\mathrm{t} \rightarrow+\infty$. I.e. in the long run domestic output $Y_{p t}$ becomes negligible as compared to foreign asset income $\mathrm{rW}_{\mathrm{Ft}}$, and national income $Y_{t} \approx r W_{t}$ grows at rate $s_{k} r>g$. It follows that $\beta_{t}=W_{t} / Y_{t} \rightarrow 1 / r$ as $t \rightarrow+\infty$.

If $r<\bar{r}$, i.e. if $g-s_{k} r>0$, then this dynamic equation admits a unique steady-state $\beta_{F^{*}}$, with:

$$
\beta_{F}^{*}=(s-g \alpha / r) /\left(g-s_{K} r\right) .=s\left(1-r^{*} / r\right) /\left(g-s_{K} r\right)
$$

Note that $\beta_{F}{ }^{*}>0$ if $r>r^{*}$ and $\beta_{F}^{*}<0$ if $r<r^{*}$ (where $r^{*}=\alpha g / s \leq \bar{r}$ is the closed-economy steadystate). $\beta_{\mathrm{F}}{ }^{*} \rightarrow+\infty$ as $\mathrm{r} \rightarrow \overline{\mathrm{r}}$.
Finally, we have: $\beta^{* *}=\left(\beta_{K}{ }^{*}+\beta_{F}{ }^{*}\right) /\left(1+r \beta_{F}{ }^{*}\right)=s_{L} /\left[g-r\left(s_{K}-S_{L}\right)\right]$.
With uniform savings ( $s=s_{L}=s_{K}$ ), then $\beta^{* *}=s / g=\beta^{*}$. I.e. the open economy steady-state wealth-income ratio is the same as the closed economy ratio, and does not depend on the world rate of return $r$.

If $s_{K}>s_{L}$ (resp. $s_{K}<s_{L}$ ), then $\beta^{* *}$ is an increasing (resp. decreasing) function of $r$, and is larger than the closed economy ratio iff $r>r^{*}$ (resp. $r<r^{*}$ ).

Note that $\beta^{* *} \rightarrow 1 / r$ as $r \rightarrow \bar{r}$. Note also that the class saving case ( $s_{L}=0 \& s_{K}>0$ ) is degenerate: if $r>\bar{r}=r^{*}$ then $\beta_{F t} \rightarrow+\infty$ as $t \rightarrow+\infty$; if $r<\bar{r}$ then $\beta_{\mathrm{Ft}} \rightarrow 0$ as $t \rightarrow+\infty$.

Example: $\mathrm{g}=2 \%, \mathrm{~s}=\mathrm{s}_{\mathrm{K}}=\mathrm{s}_{\mathrm{L}}=12 \%, \alpha=30 \%$. In the closed-economy, $\beta^{*}=\mathrm{s} / \mathrm{g}=600 \%$ and $r^{*}=\alpha / \beta^{*}=5 \%$. Now assume the economy opens up and faces a world rate of return $r=6 \%$. Then the domestic capital-output ratio $\beta_{K}{ }^{*}$ declines to $\alpha / r=500 \%$, and wealth-holders accumulate foreign assets equivalent to $\beta_{F}{ }^{*}=156 \%$ of domestic output, bringing $r \beta_{F}{ }^{*}=9 \%$ additional income. The wealth-income ratio $\beta^{* *}=\left(\beta_{K}{ }^{*}+\beta_{\mathrm{F}}{ }^{*}\right) /\left(1+\mathrm{r} \beta_{\mathrm{F}}{ }^{*}\right)$ is unchanged at $600 \%$. Now assume $\mathrm{g}=2 \%, \mathrm{~s}_{\mathrm{K}}=24 \%$ and $\mathrm{s}_{\mathrm{L}} \mathrm{such}^{2}$ that $\mathrm{s}=12 \% ~\left(\mathrm{~s}_{\mathrm{L}} \approx 9 \%\right)$. Then as the economy opens up, $\beta_{K}{ }^{*}$ still declines from $600 \%$ to $500 \%$, but $\beta_{F}{ }^{*}$ now rises to $250 \%$ (bringing that $\mathrm{r} \beta_{\mathrm{F}}{ }^{*}=15 \%$ additional income), so that the wealth-income ratio $\beta^{* *}$ rises to $652 \%$.
(ii). Inheritance ratios The formulas for the age-wealth profile $w_{t}(a)=w_{B t}(a)+w_{L t}(a)$ are the same as in the closed economy case, except that $r^{*}$ needs to be replaced by $r$. In the case $r>\bar{r}$, then labor income $y_{L t}$ vanishes in the long run, i.e. $y_{L t} / w_{t} \rightarrow 0$ as $t \rightarrow+\infty$, and so does labor wealth $\mathrm{w}_{\mathrm{Lt}}(\mathrm{a})$ relatively to bequest wealth $\mathrm{w}_{\mathrm{Bt}}(\mathrm{a})$. So we are back to the class saving case, and $\mu_{t} \rightarrow \bar{\mu}$ as $t \rightarrow \infty$. In the case $r<\bar{r}, \mu_{t} \rightarrow \mu^{*}=\mu(g, r, \rho)$ as $t \rightarrow \infty$, with $\mu(g, r, \rho)$ given by the same formulas as in the closed economy case (except that $r^{*}$ is replaced by $r$ ):

$$
\begin{equation*}
\mu(\mathrm{g}, \mathrm{r})=\frac{1-\mathrm{e}^{-(\mathrm{g}-\mathrm{sk} \mathrm{r})(\mathrm{D}-\mathrm{A})}}{1-\mathrm{e}^{-(\mathrm{g}-\mathrm{skr}) \mathrm{H}}} \tag{E.5}
\end{equation*}
$$

The limit results as $g \rightarrow 0$ apply for the same reasons. The limit results as $r \rightarrow \bar{r}$ follow from the fact that $\beta_{F}{ }^{*} \rightarrow+\infty$ as $r \rightarrow \bar{r}$, so labor wealth $W_{L t}(a)$ again vanishes relatively to bequest wealth $w_{B t}(a)$. The results for $b_{w t}$ and $b_{y t}$ follow directly from the $\mu_{t}$ results. ${ }^{263}$ On Table E2 we provide numerical illustrations of the $\mu(\mathrm{g}, \mathrm{r})$ for various parameter values. ${ }^{264}$

## E.3. Proof of Proposition 6 (section 5.3)

(dynastic model, $\rho=1$, with borrowing)

We assume $\rho=1$. In case young agents $(A \leq a<1)$ cannot borrow against future inheritance receipts, then the cross-sectional age-wealth profile $w_{t}(a)$ is the same as with class saving:

If If $a \in\left[A, I\left[\quad w_{t}(a)=0\right.\right.$
If If $a \in[I, D] \quad w_{t}(a)=\bar{w}_{t}=\bar{\mu} w_{t}$
But in case young agents are allowed to borrow against future inheritance, then they will choose to do so as soon as they become adult. We assume perfect foresight and solve for the corresponding steady-state. Consider agents belonging to a given cohort $x$. They know from the beginning of their adult life that they will receive (average) inheritance $b^{x}$ at age $a=I$. They choose a consumption path $c^{x}(a)(A \leq a \leq D)$ in order to maximize dynastic utility, anticipating that their offspring will do the same. ${ }^{265}$ Utility maximization implies that they will choose a consumption path growing at rate $g_{c}=\left(r_{t}-\theta\right) / \sigma$, i.e. at rate $g_{c}=g$ since we look

[^163]at steady-state paths with $r_{t}=r^{*}=\theta+\sigma g$. That is, they choose a consumption path of the form: $c^{x}(a)=c^{x}(A) e^{g(a-A)}$. One possibility would be to set their initial consumption level $c^{x}(A)$ equal to a fraction $r^{*}-g$ of the present value of their bequest $\left(c^{x}(A)=\left(r^{*}-g\right) b^{x} e^{-r^{*}(1-A)}\right)$, which by definition corresponds to a consumption path that can be sustained for ever. But they need to anticipate that their children will do the same, i.e. they will also start consuming their bequest before they receive it. ${ }^{266}$ So the time-consistent utility maximizing consumption path $c^{x}(a)=c^{x}(A) e^{g(a-A)}$ must be such that cohort $x$ leaves bequest $b^{x+H}$ allowing the next generation to pursue the same consumption path, i.e. such that $b^{x+H}=$ $b^{x} e^{g H}$. Now, for given $c^{x}(A)$, the wealth path $w^{x}(a)$ followed by cohort $x$ will look as follows:
If $a \in\left[A, I\left[\quad w^{x}(a)=-\int_{A \leq a^{\prime} \leq a} C^{x}(A) e^{g\left(a^{\prime}-A\right)} e^{r^{*}\left(a-a^{\prime}\right)} d a^{\prime}\right.\right.$
If $a \in[I, D] \quad w^{x}(a)=b^{x} e^{r^{*}(a-I)} \quad-\int_{A \leq a^{\prime} \leq a} C^{x}(A) e^{g\left(a^{\prime}-A\right)} e^{r^{x^{*}}\left(a-a^{\prime}\right)} d a^{\prime}$
That is:
If $a \in\left[A, I\left[\quad w^{x}(a)=-c^{x}(A) \frac{e^{r^{*}(a-A)}-e^{g(a-A)}}{r^{*}-g}\right.\right.$
If $a \in[I, D] \quad w^{x}(a)=b^{x} e^{r^{*}(a-1)}-c^{x}(A) \frac{e^{r^{*}(a-A)}-e^{g(a-A)}}{r^{*}-g}$
Note that wealth $w^{x}(a)$ is negative until inheritance age (as cohort $x$ borrows against future inheritance) and positive afterwards. Wealth at death $w^{x}(D)$ left by cohort $x$ is by definition equal to the bequest $b^{x+H}$ received by the next generation:
$$
b^{x+H}=w^{x}(D)=b^{x} e^{x^{*} H}-c^{x}(A) \frac{e^{r^{*}(D-A)}-e^{g(D-A)}}{r^{*}-g}
$$

The consumption path is time consistent iff $b^{x+H}=b^{x} e^{g H}$, i.e. iff:
$c^{x}(A)=\left(r^{*}-g\right) \frac{e^{r^{*} H}-e^{g H}}{e^{*^{*}(D-A)}-e^{g(D-A)}} b^{x}$
Note that this is lower than $\left.\left(r^{*}-g\right) b^{x} e^{-r^{*}(1-A)}\right)$, i.e. time consistency forces to choose lower consumption path.

We can now compute the resulting cross-sectional wealth profile $w_{t}(a)$. Individuals who are a-year-old at time $t$ belong to cohort $x=t-a$, and they will receive (or have received) inheritance $b^{x}=b_{t} e^{g(l-a)}$ at time $t+l-a$ (at age $\left.I\right)$. So we have:

If $a \in\left[A, I\left[\quad w_{t}(a)=-b_{t} e^{g(1-A)} \frac{e^{r^{* H}}-e^{g H}}{e^{r^{*}(D-A)}-e^{g(D-A)}} \quad\left[e^{\left(r^{*}-g\right)(a-A)}-1\right]\right.\right.$

[^164]If $a \in[I, D] \quad w_{t}(a)==b_{t}\left[e^{\left(r^{*}-g\right)(a-1)}-e^{g(1-A)} \frac{e^{r^{*} H}-e^{g H}}{e^{r^{*}(D-A)}-e^{g(D-A)}}\left[e^{\left(r^{*}-g\right)(a-A)}-1\right]\right]$
If we now compute average wealth $w_{t}=\int_{A \leq a \leq D} W_{t}(a)$ da and the ratio $\mu_{t}=\frac{w_{t}(D)}{w_{t}}$, we obtain the following formula for steady-state $\mu^{*}$ :

$$
\begin{equation*}
\mu^{*}=\frac{e^{\left(r^{*}-g\right)(D-A)}-1}{e^{\left(r^{*}-g\right) H}-1} \tag{E.6}
\end{equation*}
$$

Note that $\forall r^{*}-g>0, \mu^{*}>\bar{\mu}=(\mathrm{D}-\mathrm{A}) / \mathrm{H}$.
Steady-state $\mu^{*}$ is an increasing function of $r^{*}-g$.
$\mu^{*} \rightarrow \bar{\mu}$ as $r^{*}-g \rightarrow 0$ (which can occur only if $\theta \rightarrow 0$ and $g \rightarrow 0$ ).
The reason why $\mu^{*}$ is always larger than $\bar{\mu}$ when we allow for borrowing is fairly intuitive.
Because young agents borrow against future inheritance, the cross-sectional age-wealth profile $w_{t}(a)$ is negative and downward sloping from age A to I, then jumps to positive levels at age $I$, and then is upward sloping from age $I$ to age $D$ (see Figure E4). ${ }^{267}$ This pushes upwards the relative wealth of decedents $\mu_{\mathrm{t}}$ and the steady-state inheritance flows. A larger $r^{*}-g$ differential will make the downward-sloping part more steeply declining, and the upward-sloping part more steeply rising, thereby pushing $\mu_{t}$ further up. The formula shows that the effect can become very large and push steady-state $\mu^{*}$ towards very high levels, especially if life expectancy is large. E.g. with $A=20, D=70, H=30, g=2 \%$ and $r^{*}=5 \%$, one gets $\mu^{*}=239 \%$ (instead of $\bar{\mu}=167 \%$ in the case with no borrowing). But with $A=20$, $D=80, H=30, g=0 \%$ and $r^{*}=5 \%$, one gets $\mu^{*}=548 \%$ (instead of $\bar{\mu}=200 \%$ in the case with no borrowing). With $\beta^{*}=600 \%$, this would imply an aggregate inheritance flow equal to $\mathrm{b}_{\mathrm{y}}{ }^{*}=55 \%$ of national income (instead of $20 \%$ with no borrowing). We view this extreme case merely as an intellectual curiosity.

## E.4. Proof of Proposition 7 (section 5.3)

(dynastic model, $\rho \leq 1$, no borrowing)
(i) Computation of lifecycle saving rates. We now consider the case $\rho<1$. That is, instead of getting (average) labor income $y_{L t}$ during their entire adult lifetime ( $R \leq a \leq D$ ), agents now receive $y_{L t}(a)=\left(1-T_{\rho}\right) \hat{y}_{L t}$ when they are working $(A \leq a<R)$ and $y_{L t}(a)=\rho\left(1-T_{\rho}\right) \hat{y}_{L t}$ when they are retired $(R \leq a \leq D)$, with:

[^165]$\hat{y}_{L t}=\frac{D-A}{R-A} y_{L t}=$ average pre-tax labor income of adult workers at time $t$
$T_{\rho}=$ budget-balanced pension tax rate $=\frac{\rho(D-R)}{R-A+\rho(D-R)}$
With $\rho=0$ they receive no pension at all. With $\rho=1$ we are back to the previous case.
Consider agents belonging to a given cohort x . We assume that young agents cannot borrow against future inheritance. More precisely, we assume that they behave until age I as if they were not going to receive any inheritance; so in effect they maximize twice their dynastic utility function: once at age A (under the anticipation that they will receive no inheritance), and once at age I (in case they receive inheritance they revise their plan). ${ }^{268}$ Utility maximization at age A implies that they will choose a consumption path $c^{x}(a)=c^{x}(A) e^{g(a-A)}$ growing at rate $g$ during their entire lifetime. ${ }^{269}$ To achieve this goal, they save a fraction $S_{L} y_{L}{ }^{x}(a)$ of their labor income when they are working ( $A \leq a<R$ ), in order to finance an extra consumption flow $C_{L}{ }^{x}(a)$ when they are retired ( $R \leq a \leq D$ ). Since $y_{L}{ }^{x}(a)=y_{L}{ }^{x}(A) e^{g(a-A)}$ for $a \in\left[A, R\left[\right.\right.$ and $y_{L}{ }^{x}(a)=\rho y_{L}{ }^{x}(A) e^{g(a-A)}$ for $a \in[R, D]$, the extra consumption flow picked by utility maximizing agents will simply be equal to $c_{L}{ }^{x}(a)=C_{L} y_{L}{ }^{x}(A) e^{g(a-A)}$, with $c_{L}+\rho=1-s_{L}$, i.e. agents will save whatever it takes in order to complement the pension replacement rate and ensure an effective replacement rate of $100 \%$ at retirement age. ${ }^{270}$ In order to equilibrate the saving and dissaving flows, the saving rate $s_{\llcorner }$must be such that:
\[

$$
\begin{equation*}
S_{L} \int_{A \leq a \leq R} e^{\left(r^{*}-g\right)(R-a)} d a=c_{L} \int_{R \leq a \leq D} e^{\left(r^{*}-g\right)(R-a)} d a \tag{E.7}
\end{equation*}
$$

\]

Replacing $c_{L}$ by $1-s_{L}-\rho$, we get the following formula for the lifecycle saving rate $\mathrm{s}_{\mathrm{L}}$ :

$$
\begin{gather*}
\mathrm{S}_{\mathrm{L}}=(1-\rho) \overline{\mathrm{S}}_{\mathrm{L}} \\
\text { With: } \overline{\mathrm{S}}_{\mathrm{L}}=\frac{1-\mathrm{e}^{-\left(\mathrm{r}^{*}-\mathrm{g}\right)(\mathrm{D}-\mathrm{R})}}{\mathrm{e}^{\left(\mathrm{r}^{*}-g\right)(R-A)}-\mathrm{e}^{-\left(\mathrm{r}^{*}-g\right)(D-R)}} \tag{E.8}
\end{gather*}
$$

In case the pension system offers 100\% replacement rate ( $\rho=1$ ), then there is no need for lifecycle saving ( $s_{L}=0$ ). Conversely if there is no pension system ( $\rho=0$ ), then lifecycle

[^166]savings takes its maximal value $\bar{s}_{L}$. Note that as long as $r^{*}-g>0, \bar{s}_{L}<\bar{T}_{p}=\frac{D-R}{D-A}$, i.e. the private savings rate delivering $100 \%$ replacement rate at retirement is less than the pension tax rate delivering the same outcome. This is a direct consequence of the fact that the internal rate of return of unfunded pay-as-you-go pension system is equal to g , while the rate of return on private savings is equal to $r^{*}$. In case $r^{*}-g \rightarrow 0$ (which in the steadycase of the dynastic model requires $r^{*}=g=\theta=0$ ), then $\bar{s}_{L} \rightarrow \bar{T}_{p}=\frac{D-R}{D-A}$. Conversely, other things equal, the higher $r^{*}-\mathrm{g}$, the lower $\overline{\mathrm{s}}_{\mathrm{L}}$.

Example: Take $A=20, R=60, D=80$. Then if $r^{*}-g=0, \bar{s}_{L}=\bar{T}_{p}=33 \%$. If $r^{*}-g=1 \%$, then $\bar{T}_{p}$ is still equal to $33 \%$, but $\bar{s}_{\mathrm{L}}=27 \%$. If $\mathrm{r}^{*}-\mathrm{g}=3 \%$ (say, $\mathrm{g}=2, \mathrm{r}^{*}=5 \%$ ), then $\overline{\mathrm{s}}_{\mathrm{L}}=16 \%$ (see Table E3).
(ii) Computation of lifecycle wealth. Once we know $s_{L}$, the longitudinal age profile of lifecycle wealth $w_{L}{ }^{\mathrm{X}}(a)$ follows:
If $a \in[A, R] \quad W_{L}{ }^{x}(a)=s_{L} y_{L}{ }^{x}(A) \int_{A \leq a^{\prime} \leq a} e^{g\left(a^{\prime}-A\right)} e^{r^{*}\left(a-a^{\prime}\right)} d a^{\prime}$
If $a \in[R, D] \quad w_{L}{ }^{x}(a)=s_{L} y_{L}{ }^{x}(A) \int_{A \leq a^{\prime} \leq R} e^{g\left(a^{\prime}-A\right)} e^{r^{r^{*}\left(a-a^{\prime}\right)}} d a^{\prime}-C_{L} y_{L}{ }^{x}(A) \int_{R \leq a^{\prime} \leq a} e^{g\left(a^{\prime}-A\right)} e^{r^{*}\left(a-a^{\prime}\right)} d a$
Replacing $c_{L}$ by $1-s_{L}-\rho$ and $s_{L}$ by $(1-\rho) \bar{s}_{L}$, we get:
If $a \in[A, R] \quad w_{L}{ }^{x}(a)=(1-\rho) \bar{S}_{L} y_{L}{ }^{x}(A) e^{g(a-A)} \frac{e^{\left(r^{*}-g\right)(a-A)}-1}{r^{*}-g}$
If $a \in[R, D] \quad w_{L}{ }^{x}(a)=(1-\rho) y_{L}{ }^{x}(A) e^{g(a-A)}\left[\bar{s}_{L} \frac{e^{\left(r^{*}-g\right)(a-A)}-1}{r^{*}-g}-\frac{e^{\left(r^{*}-g\right)(a-R)}-1}{r^{*}-g}\right]$
With $\rho=1$ there is no lifecycle wealth. With $\rho<1$, lifecycle wealth $w_{L}{ }^{x}(a)$ has the usual humpshaped profile: it rises from zero at age $a=A$ to a maximum $w_{L}{ }^{x}(R)$ at retirement age $a=R$, and then declines towards zero at death age $a=D$. In case $r^{*}-g \rightarrow 0$, then we get the standard Modigliani triangle:
If $a \in[A, R] \quad w_{L}{ }^{x}(a)=(1-\rho) \bar{s}_{L} \quad y_{L}{ }^{x}(A)(a-A)=(1-\rho) \frac{D-R}{D-A} y_{L}{ }^{x}(A)(a-A)$
If $a \in[R, D] \quad w_{L}{ }^{x}(a)=(1-\rho) y_{L}{ }^{x}(A)\left[\bar{s}_{L}(a-A)-(a-R)\right]=(1-\rho) \frac{R-A}{D-A} y_{L}{ }^{x}(A)(D-a)$
We can now compute the resulting cross-sectional age profile of lifecycle wealth $\mathrm{w}_{\mathrm{Lt}}(\mathrm{a})$. Individuals who are a-year-old at time $t$ belong to cohort $x=t-a$, and they received labor income $y_{L}{ }^{x}(A)=y_{L t} e^{-g(a-A)}$ at time $t+A-a$ (at age $A$ ). So we have:

If $a \in[A, R] \quad w_{L t}(a)=(1-\rho) \bar{S}_{L} y_{L t} \frac{e^{\left(r^{*}-g\right)(a-A)}-1}{r^{*}-g}$
If $a \in[R, D] \quad w_{L t}(a)=(1-\rho) y_{L t}\left[\bar{s}_{L} \frac{e^{\left(r^{*}-g\right)(a-A)}-1}{r^{*}-g}-\frac{e^{\left(r^{*}-g\right)(a-R)}-1}{r^{*}-g}\right]$
From these equations we can compute average lifecycle wealth $W_{L t}=\int_{A \leq a \leq D} W_{L t}(a) d a$, and define $\beta_{L}=\frac{W_{L t}}{y_{L t}}$ the ratio between average lifecycle wealth and average labor income. We obtain the following formula:

$$
\beta_{\mathrm{L}}=\frac{\mathrm{w}_{\mathrm{Lt}}}{y_{\mathrm{Lt}}}=(1-\rho) \bar{\beta}_{\mathrm{L}}
$$

With:

$$
\begin{equation*}
\bar{\beta}_{L}=\frac{1}{D-A}\left[\bar{s}_{L} \frac{e^{\left(r^{*}-g\right)(D-A)}-1-\left(r^{*}-g\right)(D-A)}{\left(r^{*}-g\right)^{2}}-\frac{e^{\left(r^{*}-g\right)(D-R)}-1-\left(r^{*}-g\right)(D-R)}{\left(r^{*}-g\right)^{2}}\right] \tag{E.9}
\end{equation*}
$$

$\beta_{\llcorner }$measures the number of years of labor income which is being accumulated in lifecycle wealth in this economy. $\bar{\beta}_{\mathrm{L}}$ is the maximum value of $\beta_{\mathrm{L}}$, i.e. the value prevailing in the absence of a pay-as-you-go pension system ( $\rho=0$ ). As the pension system becomes more and more generous $(\rho \rightarrow 1), \beta_{\mathrm{L}}=(1-\rho) \bar{\beta}_{\mathrm{L}}$ declines linearly towards zero.
In case $r^{*}-g \rightarrow 0$, then $\bar{\beta}_{L} \rightarrow=\frac{1}{D-A}\left[\bar{s}_{L} \frac{(D-A)^{2}}{2}-\frac{(D-R)^{2}}{2}\right]=\frac{(D-R)(R-A)}{2(D-A)}$
This is the standard Modigliani triangle formula: in an economy with zero growth and zero rate of return, then in order to consume as much during retirement as during their working life, then individuals need to accumulate lifecycle wealth equivalent to (D-R)/2 years of labor income, where D-R is retirement length. ${ }^{271}$

Example: Assume $r^{*}-g=0 \%, A=20, R=60$. With $D=70$, then $\bar{\beta}_{L}=400 \%$. That is, lifecycle wealth equals $400 \%$ of aggregate labor income. With $D=80$, then $\bar{\beta}_{L}=667 \%$. If $r^{*}-g>0$, then the capitalization effect allows to lifecycle savers to save less, and the economy as a

[^167]whole to accumulate lower lifecycle wealth. So for instance if $r^{*}-g=3 \%$ (say, because $g=2 \%$ and $r^{*}=5 \%$ ), then $\bar{\beta}_{L}=332 \%$ with $D=70$ and $\bar{\beta}_{L}=568 \%$ with $D=80$ (see Table E3).

Note that $\bar{S}_{\llcorner }$and $\bar{\beta}_{\llcorner }$depends solely on the differential $r^{*}-g$, and not on the absolute level of either $r^{*}$ or $g$. Also note that a rise in $r^{*}-\mathrm{g}$ does not have a huge impact on the quantitative magnitudes: $\bar{\beta}_{\mathrm{L}}$ declines, but not that much. ${ }^{272}$

Note also that if we want to compute maximal lifecycle wealth $\mathrm{w}_{\mathrm{Lt}}$ as a fraction of national income $y_{t}$ rather than labor income $y_{L t}$, then we need to multiply $\bar{\beta}_{\mathrm{L}}$ by the labor share 1- $\alpha$. So for instance with $\alpha=30 \%$ and $r^{*}-g=3 \%$, we have (1- $\alpha$ ) $\bar{\beta}_{L}=232 \%$ with $D=70$ and (1a) $\bar{\beta}_{\mathrm{L}}=398 \%$ with $\mathrm{D}=80$. If we now want to compute actual lifecycle wealth (given the existence of a pay-as-you-go pension system in the model), then we need to multiply (1$\alpha) \bar{\beta}_{L}$ by $1-\rho$. So for instance with $\rho=80 \%, \alpha=30 \%$ and $r^{*}-g=3 \%$, we have $(1-\alpha) \bar{\beta}_{L}=46 \%$ with $D=70$ and $(1-\alpha) \bar{\beta}_{L}=80 \%$ with $D=80$. With $\rho=50 \%$, we get $116 \%$ and $199 \%$.
(iii) Computation of inheritance ratios. Finally, we can compute the total age-wealth profile $\mathrm{w}_{\mathrm{t}}(\mathrm{a})$ and the $\mu_{\mathrm{t}}$ ratio. The utility-maximizing profile of consumption must grow at rate g , so after they receive their inheritance, agents save a fraction $s_{K}=g / r^{*}$ of the corresponding flow return (and consume the rest). So the growth and saving effect again compensate each other, and the age profile of bequest wealth $\mathrm{w}_{\mathrm{Bt}}(\mathrm{a})$ is flat above inheritance age, in the same way as in the class saving model:

If $a \in\left[A, I\left[\quad W_{B t}(a)=0\right.\right.$
If $a \in[I, D] \quad w_{B t}(a)=b_{t}$
The total age-wealth profile $\mathrm{w}_{\mathrm{t}}(\mathrm{a})$ is given by summing up the two profiles:
$\forall a \in[A, D] \quad w_{t}(a)=w_{B t}(a)+w_{L t}(a)$
Computing the averages over all ages we have:

$$
w_{t}=\frac{H}{D-A} b_{t}+w_{L t}
$$

Replacing $w_{L t}$ by $(1-\alpha) \beta_{L} y_{t}$ and $w_{t} / y_{t}$ by its steady-state value $\beta^{*}$, we obtain that $\mu_{t}=b_{t} / w_{t}$ has a unique steady-state level $\mu^{*}$ given by:

[^168]\[

$$
\begin{equation*}
\mu^{*}=\bar{\mu}\left[1-\frac{(1-\alpha) \beta_{\mathrm{L}}}{\beta^{*}}\right]=\bar{\mu}\left[1-\frac{(1-\rho)(1-\alpha) \bar{\beta}_{\mathrm{L}}}{\beta^{*}}\right] \tag{E.10}
\end{equation*}
$$

\]

On Table E4 we provide numerical illustrations for this formula, using various values of the replacement rate $\rho .{ }^{273}$ On Figures E5-E8 we show the steady-state age-wealth profiles: with $\rho$ close to $100 \%$, then hump-shaped lifecycle wealth is not very large and has little impact on the overall age-wealth profile; but as $\rho \rightarrow 0 \%$ lifecycle wealth plays a larger role and the overall profile becomes more and more hump-shaped. ${ }^{274}$ Note that $\mu^{*}$ is always higher for lower growth rates g . This is because the ratio $\frac{(1-\alpha) \bar{\beta}_{\mathrm{L}}}{\beta^{*}}$ (i.e. the share of maximal lifecycle wealth in aggregate wealth) is an increasing function of the growth rate. ${ }^{275}$ The intuition is again that higher growth favours new savings relatively to inheritance. However the impact of $g$ on $\mu^{*}$ is smaller than in the exogenous saving model. In particular, as $g \rightarrow 0, \mu^{*}$ does not converge toward $\bar{\mu}$ : lifecycle wealth remains strictly positive, so $\mu^{*}$ remains strictly below $\bar{\mu}$.

## E.5. Proof of Propositions 8-9 (section 5.4)

(wealth-in-the-utility model)
(i) open economy, $\rho=1$, with borrowing. We start with the open economy case, which is easier to solve in the wealth-in-the-utility model, and we assume $\rho=1$ (i.e. we shut down the lifecycle saving motive). We also start by assuming that young agents can borrow against future inheritance, and we assume perfect foresight about future inheritance receipts. Consider agents belonging to a given cohort $x$. During their lifetime ( $a \in[A, D]$ ) they receive (average) labor income flows $y_{L}{ }^{x}(a)=y_{L}{ }^{x}(A) e^{g(a-A)}$. At age $a=l$ they receive

[^169](average) bequest $b^{x}$, with capitalized end-of-life value $b^{x} e^{r H}$. We note $\tilde{y}_{\mathrm{L}}{ }^{x}$ the end-of-life capitalized value of their labor income flows $y_{L}{ }^{x}(a)$ :
$$
\tilde{y}_{L}{ }^{x}=\int_{A \leq a \leq D} e^{r(D-a)} y_{L}{ }^{x}(a) d a=y_{L}{ }^{x}(A) e^{r(D-A)} \frac{1-e^{-(r-g)(D-A)}}{r-g}
$$

We note $\tilde{y}^{x}=\tilde{y}_{L}{ }^{x}+b^{x} e^{r H}$ their total lifetime resources (capitalized at the end of life). At age $a=A$ they maximize $V\left(U_{c}, W^{x}(D)\right)$ in order to allocate $\tilde{y}$ between their lifetime consumption flows $c^{x}(a)(a \in[A, D])$ and their end-of-life wealth $w^{x}(D)$. With $U_{C}=\left[\int_{A \leq a \leq D} e^{-\theta(a-A)} c^{x}(a)^{1-\sigma} d a\right]^{\frac{1}{1-\sigma}}$, standard first-order conditions imply that they will that they will choose a consumption path $c^{x}(a)=c^{x}(A) e^{g_{c}(a-A)}$ growing at rate $g_{c}=(r-\theta) / \sigma$ during their lifetime. Note that $(1-\sigma) g_{c}-$ $\theta=g_{c}-r$. The utility value $U_{c}$ of this consumption flow is given by:

$$
U_{c}=\left[\int_{A \leq a \leq D} e^{-\theta(a-A)} c^{x}(a)^{1-\sigma} d a\right]^{\frac{1}{1-\sigma}}=c^{x}(A)\left(\frac{1-e^{-\left(r-g_{c}\right)(D-A)}}{r-g_{c}}\right)^{\frac{1}{1-\sigma}}
$$

We note $\tilde{c}^{x}$ the end-of-life capitalized value of consumption flows $c^{x}(a)=c^{x}(A) e^{g_{c}(a-A)}$ :

$$
\tilde{c}^{x}=\int_{A \leq a \leq D} e^{r(D-a)} c^{x}(a) d a=c^{x}(A) e^{r(D-A)} \frac{1-e^{-\left(r-g_{c}\right)(D-A)}}{r-g_{c}}
$$

The lifetime budget constraint is: $\tilde{c}^{x}+w^{x}(D) \leq \widetilde{y}^{x}$
Maximization of $\mathrm{V}\left[\mathrm{U}_{\mathrm{C}}, \mathrm{w}^{\mathrm{x}}(\mathrm{D})\right]=\left(1-\mathrm{S}_{\mathrm{B}}\right) \log \left(\mathrm{U}_{\mathrm{C}}\right)+\mathrm{S}_{\mathrm{B}} \log \left[\mathrm{w}^{\mathrm{x}}(\mathrm{D})\right]$ implies:
$w^{x}(D)=s_{B} \tilde{y}^{x}$ and $\tilde{c}^{x}=\left(1-s_{B}\right) \tilde{y}^{x}$.
Thanks to linearity, the consumption profile can be broken down into bequest-financed and labor-financed consumption (each flow growing at rate $\left.g_{c}\right)$ : $c^{x}(a)=c_{B}{ }^{x}(a)+c_{L}{ }^{x}(a)$. We have: $c^{x}(A)=c_{B}{ }^{x}(A)+c_{L}{ }^{x}(A)$
$C_{B}{ }^{x}(A)=\left(1-S_{B}\right) \frac{r-g_{c}}{1-e^{-\left(r-g_{c}\right)(D-A)}} b^{x} e^{-r(1-A)}$
$c_{L}{ }^{x}(A)=\left(1-s_{L}\right) y_{L}{ }^{\mathrm{X}}(A)$
with: ${ }^{276}$

$$
\begin{equation*}
1-s_{L}=\left(1-s_{B}\right) \frac{\left(r-g_{c}\right)\left(1-e^{-(r-g)(D-A)}\right)}{(r-g)\left(1-e^{-\left(r-g_{c}\right)(D-A)}\right)} \tag{E.11}
\end{equation*}
$$

The wealth profile $w^{x}(a)$ can be be written: $w^{x}(a)=w_{B}{ }^{x}(a)+w_{L}{ }^{x}(a)$, where $w_{B}{ }^{x}(a)$ is bequest wealth (i.e. the non-consumed part of capitalized bequest ressources at age a) and $w_{L}{ }^{\mathrm{X}}(a)$ is labor wealth (i.e. the non-consumed part of capitalized labor ressources at age a):
$\forall a \in[A, D], w_{L}{ }^{x}(a)=\int_{A \leq a^{\prime} \leq a} e^{r\left(a-a^{\prime}\right)} y_{L}{ }^{x}\left(a^{\prime}\right) d a-\int_{A \leq a^{\prime} \leq a} e^{r\left(a-a^{\prime}\right)} c_{L}{ }^{x}\left(a^{\prime}\right) d a$
I.e. $\forall a \in[A, D], w_{L}{ }^{x}(a)=y_{L}{ }^{x}(A) e^{r(a-A)}\left[\frac{1-e^{-(r-g)(a-A)}}{r-g}-\left(1-S_{L}\right) \frac{1-e^{-\left(r-g_{c}\right)(a-A)}}{r-g_{c}}\right]$
$\forall a \in\left[A, I\left[, w_{B}{ }^{X}(a)=-\int_{A \leq a^{\prime} \leq a} e^{r\left(a-a^{\prime}\right)} c_{B}{ }^{x}\left(a^{\prime}\right) d a=-b^{x} e^{r(a-1)}\left(1-s_{B}\right) \frac{1-e^{-\left(r-g_{c}\right)(a-A)}}{1-e^{-\left(r-g_{c}\right)(D-A)}}\right.\right.$
$\forall a \in[I, D], w_{B}{ }^{x}(a)=b^{x} e^{r(a-l)}-\int_{A \leq a^{\prime} \leq a} e^{r\left(a-a^{\prime}\right)} c_{B}{ }^{x}\left(a^{\prime}\right) d a=b^{x} e^{r(a-l)}\left[1-\left(1-S_{B}\right) \frac{1-e^{-\left(r-g_{c}\right)(a-A)}}{1-e^{-\left(r-g_{c}\right)(D-A)}}\right]$
Wealth-at-death $w^{x}(D)$ left by cohort $x$ to cohort $x+H$ follows a simple dynamic equation:
$w^{x}(D)=w_{B}{ }^{x}(D)+w_{L}{ }^{x}(D)=b^{x+H}=s_{B} \widetilde{y}^{x}=s_{B}\left(\tilde{y}_{L}{ }^{x}+b^{x} e^{r H}\right)$
I.e. $b^{x+H}=s_{B} \tilde{y}_{L}{ }^{x}+s_{B} e^{r H} b^{x}$

At time $t$, the cohort receiving bequest $b_{t}$ is the cohort born at time $x=t-l$. This cohort started working with labor income $y_{L}{ }^{\mathrm{x}}(\mathrm{A})=\mathrm{y}_{\mathrm{Lt}} \mathrm{e}^{-\mathrm{g}(1-\mathrm{A})}$ and their lifetime labor resources can be rewritten as follows:
$\tilde{y}_{L}{ }^{x}=y_{L}{ }^{x}(A) e^{r(D-A)} \frac{1-e^{-(r-g)(D-A)}}{r-g}=\lambda(D-A) e^{r H} y_{L t}$
With:

$$
\begin{equation*}
\lambda=\frac{e^{(r-g)(1-A)}-e^{-(r-g)(D-1)}}{(r-g)(D-A)} \tag{E.12}
\end{equation*}
$$

The dynamic equation can be rewritten: $b_{t+H}=s_{B} \lambda(D-A) e^{r H} y_{L t}+s_{B} e^{r H} b_{t}$
Noting that $y_{L t}=(1-\alpha) y_{p t}$ (where $y_{p t}$ is per adult domestic income, which in the open economy case differs from per adult national income $y_{t}=y_{p t}+r\left(w_{t}-k_{t}\right)$ ), ${ }^{277}$ we find the following dynamic equation for the inheritance flow-domestic income ratio $b_{y t}=m_{t} b_{t} / y_{p t}$ :

$$
\begin{equation*}
b_{y t+H}=S_{\mathrm{B}} \lambda(1-\alpha) e^{(r-g) H}+S_{\mathrm{B}} e^{(r-g) H} b_{y t} \tag{E.13}
\end{equation*}
$$

This process converges iff $s_{B} e^{(r-g) H}<1$, i.e. iff $r<\bar{r}(g)=\bar{r}+g$, with $\bar{r}=-\log \left(s_{B}\right) / H$.

[^170]Example: With $\mathrm{s}_{\mathrm{B}}=10 \%$ and $\mathrm{H}=30$, then $\overline{\mathrm{r}}=7.7 \%$. With $\mathrm{g}=0 \%$ the process converges iff the world rate of return $r$ is less than $7.7 \%$. With $g=1 \%$, it needs to be less than $8.7 \%$.

If $r>\bar{r}(g)$, then as $t \rightarrow+\infty, b_{y t} \rightarrow+\infty$.
If $r<\bar{r}(g)$, then as $t \rightarrow+\infty, b_{y t} \rightarrow b_{y}{ }^{*}$, with: $\quad b_{y}{ }^{*}=b_{y}(g, r)=\frac{s_{B} \lambda(1-\alpha) e^{(r-g) H}}{1-s_{B} e^{(r-g) H}}$
One can see that $b_{y}{ }^{\prime}(g)<0$ and $b_{y}{ }^{\prime}(r)<0$. Note that the steady-state inheritance-income ratio $b_{y}{ }^{*}$ depends only on the gap $r-g$, not on the absolute levels of $r$ and $g$. Numerical computations show that $b_{y}{ }^{*}$ is a steeply rising function of $r-g$. E.g. with $s_{B}=10 \%$ and $\mathrm{H}=30$, then $b_{y}{ }^{*}=8 \%$ if $r-g=0 \%, b_{y}{ }^{*}=26 \%$ if $r-g=3 \%$ and $b_{y}{ }^{*}=81 \%$ if $r-g=5 \%$ (see Table E5).
Note however that the very high values of $b_{y}{ }^{*}$ obtained for $r-g=5 \%$ are partly due to the fact that the $b_{y}{ }^{*}$ ratio given by equation (E.13) uses the domestic income denominator (rather than national income, which for high r-g is much larger than domestic income). When we look at the $\overline{\mathrm{b}}_{\mathrm{y}}{ }^{*}$ ratio (which we define using the national income denominator), then we find less extreme quantitative impact of r-g. ${ }^{278}$

One can then use the longitudinal profile $w^{x}(a)$ equations in order to compute crosssectional age-wealth profiles $\mathrm{w}_{\mathrm{t}}(\mathrm{a})$, and from there obtain closed form analytical formulas for the steady-state ratios $\mu_{\mathrm{t}}=\mathrm{b}_{\mathrm{t}} / \mathrm{w}_{\mathrm{t}}$ and $\beta_{\mathrm{t}}=\mathrm{w}_{\mathrm{t}} / \mathrm{y}_{\mathrm{t}}$. This is what we do below for the case without borrowing, which we view as more realistic. The $\mathrm{b}_{\mathrm{y}}{ }^{*}$ formula turns out to be the same without or with borrowing. However the formulas for $\mu^{*}$ and $\beta^{*}$ are different. One can easily adapt the no-borrowing $\mu^{*}$ and $\beta^{*}$ formulas given below to the borrowing case. In particular, in the same way as in the dynastic model, $\mu^{*}$ will be larger in the borrowing case. When borrowing from future inheritance is allowed, then $w_{B}{ }^{\mathrm{X}}(a)<0$ for $a<1$ (i.e. young agents borrow in order to raise their consumption, see formulas above), which pushes upwards the steady-state relative wealth of decedents. The difference with the dynastic model is that there will also be less aggregate wealth accumulation ( $\beta^{*}$ will be lower in the borrowing case), so that $b_{y}{ }^{*}$ is unaffected.
(ii) open economy, $\rho=1$, no borrowing. We now assume that young agents cannot borrow against future inheritance. More precisely, in the same way as in the dynastic model, we assume that they behave until age $I$ as if they were not going to receive any inheritance;

[^171]so in effect they maximize twice their utility function $V\left(U_{c}, w(D)\right)$ : once at age $A$ (under the anticipation that they will receive no inheritance), and once at age I (in case they receive inheritance, they revise their consumption plans accordingly).
Consider agents belonging to a given cohort x . Utility maximization at age A implies that they again choose a consumption path $c^{x}(a)=c^{x}(A) e^{g_{c}(a-A)}$ growing at rate $g_{c}=(r-\theta) / \sigma$. The utility value $U_{c}$ of this consumption flow is the same as before. The formulas for end-of-life capitalized values $\widetilde{\mathrm{c}}^{\mathrm{x}}$ and $\tilde{\mathrm{y}}_{\mathrm{L}}{ }^{\mathrm{x}}$ are the same as before. The only difference is that $\widetilde{\mathrm{y}}^{\mathrm{x}}=\widetilde{\mathrm{y}}_{\mathrm{L}}{ }^{\mathrm{x}}$, i.e. there is no anticipated bequest, so total expected resources are equal to labor income resources. So we have $\tilde{c}^{x}=\left(1-s_{B}\right) \tilde{y}_{L}{ }^{x}$, i.e. $c_{L}{ }^{x}(A)=\left(1-S_{L}\right) y_{L}{ }^{x}(A)$ (with $1-s_{L}$ is given by the same formula as in the borrowing case) and $c_{B}{ }^{x}(A)=0$. The longitudinal age-wealth profile $w^{x}(a)$ can again be written $w^{x}(a)=w_{B}{ }^{x}(a)+w_{L}{ }^{x}(a)$, but $w_{B}{ }^{x}(a)=0$ (for all $\left.a \in[A, I]\right)$, so that:

For all $a \in[A, I], w^{x}(a)=w_{L}{ }^{x}(A)=y_{L}{ }^{x}(A) e^{r(a-A)}\left[\frac{1-e^{-(r-g)(a-A)}}{r-g}-\left(1-s_{L}\right) \frac{1-e^{-\left(r-g_{c}\right)(a-A)}}{r-g_{c}}\right]$

At age $a=I$, cohort $x$ receives average bequest $b^{x}$, with capitalized end-of-life value $b^{x} e^{r H}$. They revise their plans and choose a new consumption path $c^{x}(a)=c^{x}(I) e^{g_{c}(a-l)}$ growing at rate $g_{c}$. The rest-of-life budget constraint is: $\tilde{c}^{\prime}+w^{x}(D) \leq \tilde{y}^{\prime}=\tilde{y}_{L}{ }^{\prime}+w^{x}(I) e^{r H}+b^{x} e^{r H}$

With: $\tilde{y}_{L}{ }^{\prime}=\int_{I \leq a \leq D} e^{r(D-a)} y_{L}{ }^{x}(a) d a=y_{L}{ }^{x}(I) e^{r H} \frac{1-e^{-(r-g) H}}{r-g}$,
$\tilde{c}^{\prime}=\int_{1 \leq a \leq D} e^{r(D-a)} c^{x}(a) d a=c^{x}(I) e^{r H} \frac{1-e^{-\left(r-g_{c}\right) H}}{r-g_{c}}$
Utility maximization leads to: $w^{x}(D)=s_{B} \widetilde{y}^{\prime}$ and $\widetilde{c}=\left(1-s_{B}\right) \widetilde{y}^{\prime}$, i.e.:
$C^{x}(1)=C_{B}{ }^{x}(I)+C_{L}{ }^{x}(I)$
with: $C_{B}{ }^{x}(I)=\left(1-S_{B}\right) \frac{r-g_{C}}{1-e^{-\left(r-g_{c}\right) H}} b^{x} e^{r H}$
$C_{L}{ }^{x}(I)=C_{L}{ }^{x}(A) e^{g_{c}(1-A)}=\left(1-S_{L}\right) y_{L}(A) e^{g_{c}(I-A)}$
Note that this latter equation simply follows from time consistency: individuals who do not receive any bequest at age $\mathrm{a}=\mathrm{I}$ have no reason to change their initial consumption plan. However individuals with positive bequests do adjust upward their initial consumption plan. Again thanks to linearity we can concentrate on cohort-level aggregates.

The longitudinal age-wealth profile $w^{x}(a)$ after age $a=1$ is given by:
For all $a \in[I, D], w^{x}(a)=w_{B}{ }^{x}(a)+w_{L}{ }^{x}(a)$,

With: $w_{B}{ }^{\mathrm{x}}(a)=b^{\mathrm{x}} \mathrm{e}^{\mathrm{r}(\mathrm{a-l})}\left[1-\left(1-\mathrm{s}_{\mathrm{B}}\right) \frac{1-\mathrm{e}^{-\left(r-g_{c}\right)(a-1)}}{1-\mathrm{e}^{-\left(r-g_{c}\right) H}}\right]$
$w_{L}{ }^{x}(a)=y_{L}{ }^{x}(A) e^{r(a-A)}\left[\frac{1-e^{-(r-g)(a-A)}}{r-g}-\left(1-S_{L}\right) \frac{1-e^{-\left(r-g_{c}\right)(a-A)}}{r-g_{c}}\right]$
Note that for $a=D$, we again have: $w^{x}(D)=w_{B}{ }^{x}(D)+w_{L}{ }^{x}(D)=b^{x+H}=s_{B}\left(\tilde{y}_{L}{ }^{x}+b^{x} e^{r H}\right)$
l.e. wealth at death $w^{x}(D)$ is the same as in the case with borrowing: allowing young agents to borrow against future inheritance alters the time pattern of consumption and wealth accumulation, but does not affect end of life wealth, which is always equal to a fraction $s_{B}$ of total lifetime resources. ${ }^{279}$ So the dynamic equation for the inheritanceincome ratio is the same as before $\left(b_{y t+H}=s_{B} \lambda(1-\alpha) e^{(r-g) H}+s_{B} e^{(r-g) H} b_{y t}\right)$, and we obtain the same convergence results: if $r>\bar{r}(g)$, then as $t \rightarrow+\infty, b_{y t} \rightarrow+\infty$.

If $r<\bar{r}(g)$, then as $t \rightarrow+\infty, b_{y t} \rightarrow b_{y}{ }^{*}$, with: $b_{y}{ }^{*}=b_{y}(g, r)=\frac{s_{B} \lambda(1-\alpha) e^{(r-g) H}}{1-s_{B} e^{(r-g) H}}$
In order to compute $\mu_{t}=b_{t} / w_{t}$ and $\beta_{t}=w_{t} / y_{t}$, we now need to compute the cross-sectional age-wealth profile $\mathrm{w}_{\mathrm{t}}(\mathrm{a})$. At time t , a-year-old individuals belong to cohort x -a, and their beginning of life labor income was $y_{L}{ }^{x}(A)=y_{L t} e^{-g(a-A)}$. Assuming we are in (non-explosive) steady-state $\left(b_{y t}=b_{y}{ }^{*}\right)$, at age $I$ they receive bequest $b^{x}=b_{t} e^{-g(a-1)}$. So we have:
$\forall a \in[A, I], w_{t}(a)=w_{L t}(a)=y_{L t}\left[\frac{e^{(r-g)(a-A)}-1}{r-g}-\left(1-s_{L}\right) \frac{e^{(r-g)(a-A)}-e^{-\left(g-g_{c}\right)(a-A)}}{r-g_{c}}\right]$
$\forall \mathrm{a} \in[\mathrm{l}, \mathrm{D}], \mathrm{w}_{\mathrm{t}}(\mathrm{a})=\mathrm{w}_{\mathrm{Bt}}(\mathrm{a})+\mathrm{w}_{\mathrm{Lt}}(\mathrm{a})$
With: $w_{B t}(a)=b_{t} e^{(r-g)(a-l)}\left[1-\left(1-s_{B}\right) \frac{1-e^{-\left(r-g_{c}\right)(a-1)}}{1-e^{-\left(r-g_{c}\right) H}}\right]$
$W_{L t}(a)=y_{L t}\left[\frac{e^{(r-g)(a-A)}-1}{r-g}-\left(1-S_{L}\right) \frac{e^{(r-g)(a-A)}-e^{-\left(g-g_{c}\right)(a-A)}}{r-g_{c}}\right]$
Average wealth $w_{t}$ is given by: $w_{t}=w_{B t}+w_{L t}=\frac{1}{D-A}\left[\int_{I \leq a \leq D} W_{B t}(a) d a+\int_{A \leq a \leq D} w_{L t}(a) d a\right]$

[^172]We use the same open economy notations as those introduced in proposition 4. We note $\beta_{\mathrm{t}}=\mathrm{w}_{\mathrm{t}} / \mathrm{y}_{\mathrm{t}}$ the wealth-national income ratio, $\beta_{\mathrm{pt}}=\mathrm{w}_{\mathrm{t}} / \mathrm{y}_{\mathrm{pt}}$ the wealth-domestic income ratio, $\beta_{\mathrm{Ft}}=\mathrm{W}_{\mathrm{Ft}} / \mathrm{y}_{\mathrm{pt}}$ the foreign wealth-domestic income ratio, and $\beta_{\mathrm{Kt}}=\mathrm{k}_{\mathrm{t}} / \mathrm{y}_{\mathrm{pt}}$ the domestic capitaloutput ratio. By definition $w_{t}=k_{t}+w_{F t}$ and $y_{t}=y_{p t}+\mathrm{rw}_{\mathrm{ft}}$, so $\beta_{\mathrm{pt}}=\beta_{\mathrm{Ft}}+\beta_{\mathrm{kt}}$ and $\beta_{\mathrm{t}}=\beta_{\mathrm{pt}} /\left(1+\mathrm{r} \beta_{\mathrm{Ft}}\right)$.
We also define $\beta_{\mathrm{Bt}}=\mathrm{w}_{\mathrm{Bt}} / \mathrm{y}_{\mathrm{pt}}$ and $\beta_{\mathrm{Lt}}=\mathrm{w}_{\mathrm{Lt}} / y_{\mathrm{Lt}}$.
By integrating the age-wealth profiles $\mathrm{w}_{\mathrm{Bt}}(\mathrm{a})$ and $\mathrm{w}_{\mathrm{Lt}}(\mathrm{a})$ and by dividing by $\mathrm{y}_{\mathrm{pt}}$, we obtain the following formulas for steady-state $\beta_{B}{ }^{*}$ and $\beta_{L}{ }^{*}$ :

$$
\begin{gather*}
\beta_{B}{ }^{*}=b_{y}{ }^{*}\left[\frac{e^{(r-g) H}-1}{r-g}-\frac{1-s_{B}}{1-e^{-\left(r-g_{c}\right) H}}\left(\frac{e^{(r-g) H}-1}{(r-g)}-\frac{1-e^{-\left(g-g_{c}\right) H}}{\left(g-g_{c}\right)}\right)\right]  \tag{E.14}\\
\beta_{L}{ }^{*}=\frac{1}{D-A}\left[\frac{e^{(r-g)(D-A)}-1-(r-g)(D-A)}{(r-g)^{2}}-\frac{1-s_{L}}{r-g_{c}}\left(\frac{e^{(r-g)(D-A)}-1}{r-g}-\frac{1-e^{-\left(g-g_{c}\right)(D-A)}}{g-g_{c}}\right)\right] \tag{E.15}
\end{gather*}
$$

We can then compute $\beta_{p}{ }^{*}=\beta_{B}{ }^{*}+\beta_{\mathrm{B}}{ }^{*}$ and $\mu^{*}=\mathrm{b}_{\mathrm{y}}{ }^{*} / \mathrm{m}^{*} \beta_{\mathrm{p}}{ }^{*}=(\mathrm{D}-\mathrm{A}) \mathrm{b}_{\mathrm{y}}{ }^{*} / \beta_{\mathrm{p}}{ }^{*}$.
Finally, the assumption of a Cobb-Douglas production function implies $\beta_{K}{ }^{*}=\alpha / r$, from which one can compute the foreign wealth ratio $\beta_{F}{ }^{*}=\beta_{p}{ }^{*}-\beta_{K}{ }^{*}$, the wealth-national income ratio $\beta^{*}=\beta_{\mathrm{p}}{ }^{*} /\left(1+\mathrm{r} \beta_{\mathrm{F}}{ }^{*}\right)$, and the inheritance flow-national income ratio $\widehat{b}_{\mathrm{y}}{ }^{*}=\mathrm{b}_{\mathrm{y}}{ }^{*} /\left(1+\mathrm{r} \beta_{\mathrm{F}}{ }^{*}\right)$.

Equations (E11) to (E15) solve the open-economy model for the non-explosive case $\mathrm{r}<\overline{\mathrm{r}}(\mathrm{g})$. These are closed form solutions, but there are many effects going on. In particular the full formula for $\mu^{*}$ is relatively complicated, and in general there is no reason that $\mu^{*}$ is equal to the class saving level $\bar{\mu}=\frac{D-A}{H}$, or even that $\mu^{*}=\mu(g) \rightarrow \bar{\mu}$ as $g \rightarrow 0$. In the case $g=0 \%$, the formula for $\mu^{*}$ still involves all other parameters, and not only D-A and H .

However by doing numerical calibrations using equations (E11)-(E15), one can see that higher growth and/or lower rates of return tend to reduce inheritance ( $\mu^{\prime}(\mathrm{g})<0, \mu^{\prime}(\mathrm{r})>0$ ), and that for realistic parameter values, and for low growth and/or high rates of return, then $\mu^{*}$ and $b_{y}{ }^{*}$ are relatively close to class saving levels $\bar{\mu}$ and $\beta^{*} / H$.

We report on Tables E6 and E7 two series of calibrations (parameters can be changed in the excel file). On Table E6 we assume $r=5 \%, \theta=2 \%, \sigma=5, s_{B}=10 \%$, and we make the growth rate vary from $\mathrm{g}=0 \%$ to $\mathrm{g}=5 \%$, and the demographic parameters vary from $19^{\text {th }}$
century values $(D=60, I=30)$ to $21^{\text {st }}$ century values $(D=80, I=50)$. As $g$ rises, $r-g$ declines, so the inheritance-income ratio $b_{y}{ }^{*}$ declines: as was already noted above, $b_{y}{ }^{*}$ is a steeply rising function of $r$-g. Note that the economy accumulates a lot of foreign assets when r-g is large (i.e. g small), and conversely is almost entirely owned by the rest of the world when $r-g$ is small (i.e. $g$ high). Consequently, as $g$ rises, the inheritance-income ratio $\hat{b}_{y}$ * declines in a less extreme and more realistic way than the ratio $b_{y}{ }^{*}$. E.g. $\bar{b}_{y}{ }^{*}$ goes from $31 \%$ for $g=1 \%$ to $25 \%$ for $g=2 \%$ (rather than from $44 \%$ to $26 \%$ ). We also find that the relative wealth of decedents $\mu^{*}$ rises sharply as life expectancy increases (almost as sharply as in the class saving case; see Table E1). $\mu^{*}$ is also an increasing function of $r$. Somewhat counter-intuitively, $\mu^{*}$ also appears to be on Table E6 an increasing function of g . However this is entirely due to the $\mathrm{g}_{\mathrm{c}}$ effect: i.e. as g rises from $0 \%$ to $5 \%$, the desired consumption growth rate $\mathrm{g}_{\mathrm{c}}=(\mathrm{r}-\theta) / \sigma$ remains constant at $1 \%$. So with high growth young age agents borrow enormously against future growth, thereby raising the relative wealth of the old. We are not sure that such massive borrowing patterns are realistic.

In order to shut down this effect, on Table E7 we assume that the values of $\theta$ and $\sigma$ adjust to changes in g so that $\mathrm{g}_{\mathrm{c}}$ remains permanently equal to g as g rises from $0 \%$ to $5 \%{ }^{280} \mathrm{We}$ then find that $\mu^{*}$ declines as $g$ rises. I.e. high labor income growth raises the relative wealth of the young, in the same way as in the exogenous saving and dynastic models.

In the case $r>\bar{r}(g)=\bar{r}+g$ (with $\left.\bar{r}=-\log \left(s_{B}\right) / H\right)$, then we have an explosive path: as $t \rightarrow+\infty$, $\mathrm{b}_{\mathrm{yt} \rightarrow+\infty}$ and $\beta_{\mathrm{Ft}} \rightarrow+\infty$. I.e. in the same way as in the explosive case of the exogenous saving model, domestic output $y_{p t}$ becomes negligible as compared to foreign asset income $\mathrm{rw}_{\mathrm{Ft}}$, and national income $\mathrm{y}_{\mathrm{t}} \approx \mathrm{rw} \mathrm{w}_{\mathrm{t}}$ grows at rate $\mathrm{g}_{\mathrm{r}}=\mathrm{r}-\overline{\mathrm{r}}(>\mathrm{g})$. The wealth-income ratio $\beta_{t} \rightarrow \beta^{*}=1 / r$ as $t \rightarrow+\infty$. One can also show that $\bar{b}_{y t}$ and $\mu_{t}$ converge towards some finite values $\widehat{b}_{y}{ }^{*}$ and $\mu^{*}$. All income derives from wealth, so nobody has wealth before age $I$. However there is no reason in general that the age-wealth profile $w_{t}(a)$ is flat above age $I$, so there is no reason that $\mu^{*}=\bar{\mu}$. This will occur iff $g_{c}=(r-\theta) / \sigma=g_{r}$. So for instance if $g=0 \%$,

[^173]$\theta=0 \% \sigma=+\infty$, then $\mu^{*} \rightarrow \bar{\mu}$ as $r \rightarrow \bar{r}$ (either from above or from below). But in general $\mu^{*}$ will be different from $\bar{\mu}: \mu^{*}>\bar{\mu}$ if $g_{c}<g_{r}$ and $\mu^{*}<\bar{\mu}$ if $g_{c}>g_{r}$.
(iii) closed economy, $\rho=1$, no borrowing. We now consider the closed economy case. All equations are exactly the same as in the open economy case, except that now the rate of return $r$ is no longer a free parameter. The long run steady-state $r^{*}$ is determined by the equality between the supply and the demand of capital:
\[

$$
\begin{equation*}
\beta_{\mathrm{B}}{ }^{*}(r)+\beta_{\mathrm{B}}{ }^{*}(r)=\beta_{\mathrm{K}}{ }^{*}=\alpha / r \tag{E.16}
\end{equation*}
$$

\]

Where $\beta_{B}{ }^{*}(r)$ and $\beta_{B}{ }^{*}(r)$ are given by equation (E.14) and (E.15) above. These wealth accumulation ratios are increasing functions of $r$, so the supply equals demand equation has a unique solution. Unfortunately there exists no closed form solution for $r^{*}$. The steady-state $r^{*}$ and $\beta^{*}=\alpha / r^{*}$ of the wealth-in-the-utility-function model can be larger or smaller than the dynastic model steady-state values $\hat{r}=\theta+\sigma g$ and $\hat{\beta}=\alpha / \hat{r}$, depending on the various parameters. The aggregate wealth-income ratio $\beta^{*}$ is naturally an increasing function of $s_{B}$ and a decreasing function of $g$ (and conversely for $r^{*}$ ). In case $s_{B}=0$ and $\rho=1$, then $r^{*}>\hat{r}$ (with $r=\hat{r}$ there would be no saving at all), with $r^{*}$ declining and $\rightarrow \hat{r}$ as life expectancy $\mathrm{D} \rightarrow+\infty$ (in effect the model converges toward the dynastic model). In case $\mathrm{s}_{\mathrm{B}}$ is sufficiently large, then $r^{*}<\hat{r}$ (as $s_{B} \rightarrow 1$, then $\beta^{*} \rightarrow+\infty$ and $r^{*} \rightarrow 0$ ). But if one wants to go beyond these qualitative statements, one needs to use numerical solutions in order to study closed economy steady-states.

We report on Tables E8 to E11 four series of calibrations (parameters can be changed in the excel file). On Tables E8 and E9, we assume that $\mathrm{s}_{\mathrm{B}}$ adjusts so that when g rises from $0 \%$ to $5 \%$ the steady-state $r^{*}$ and $\beta^{*}$ remain fixed at $5 \%$ and $600 \%$. On Tables E10 and E11, we assume that $s_{B}$ is fixed at $10 \%$, and we compute the equilibrium values of $r^{*}$ and $\beta^{*}$, either with fixed $\theta$ and $\sigma$ (Table E10), or by assuming that $\theta$ and $\sigma$ adjust so as to keep $g_{c}=g$ (Table E11), in the same way as in the open economy calibrations. The most striking finding is that in all variants the steady-state $b_{y}{ }^{*}$ almost does not depend on life expectancy $D$ : i.e. the decline in $\mathrm{m}^{*}$ is almost entirely compensated by the rise in $\mu^{*}$. For realistic low-growth parameter values ( $g=1 \%-2 \%, r^{*}=4 \%-5 \%, s_{B}$ around $10 \%$ ), we find that $\mu^{*}$ and $b_{y}{ }^{*}$ are extremely close to the class saving levels $\bar{\mu}$ and $\beta^{*} / H$ (or if anything slightly above class saving levels).
(iv) $\rho \leq 1$. All equations above can be extended to the case with less than $100 \%$ replacement rates, in the same way as in the dynastic model (see above). There are major differences with the dynastic model, however.

First, one can easily show that the same formula for steady-state $b_{y}{ }^{*}$ (equation (E13)) applies for any $\rho \leq 1$. This is because $\rho<1$ adds an extra lifecycle wealth term $w_{L}{ }^{\mathrm{X}}(\mathrm{a})$ in the wealth equations (with $w_{L}{ }^{x}(a)$ hump shaped, i.e. maximal at age $a=R$ and going to zero for $a=D$ ), but without affecting the fact that wealth at death $w^{x}(D)$ is equal to a fixed fraction $s_{B}$ of lifetime resources. So the dynamic equations for $b^{x+H}$ as a function of $b^{x}$ and $b_{y t+H}$ as a function of byt are wholly unaffected, and so is the steady-state formula for $b_{y}{ }^{*}$. The only change in the formula is the value of $\lambda$. With $\rho \leq 1$, we have $y_{L}{ }^{x}(a)=y_{L}{ }^{x}(A) e^{g(a-A)}$ for $a \in[A, R[$ and $y_{L}{ }^{\mathrm{x}}(\mathrm{a})=\rho \mathrm{y}_{\mathrm{L}}{ }^{\mathrm{x}}(\mathrm{A}) \mathrm{e}^{\mathrm{g}(a-A)}$ for $\mathrm{a} \in[R, D]$, so $\tilde{y}_{L}$ is now given by:
$\tilde{y}_{L}=\int_{A \leq a \leq D} e^{r(D-a)} y_{L}{ }^{x}(a) d a=y_{L}{ }^{x}(A) e^{r(D-A)}\left[\frac{1-e^{-(r-g)(R-A)}}{r-g}+\rho \frac{e^{-(r-g)(R-A)}-e^{-(r-g)(D-A)}}{r-g}\right]$

At time $t$, the cohort receiving bequest $b_{t}$ is the cohort born at $x=t-I$. This cohort started working with labor income $y_{L}{ }^{x}(A)=\frac{D-A}{R-A+\rho(D-R)} y_{L t} e^{-g(1-A)}$. So $\tilde{y}_{L}=\lambda(D-A) e^{r H} y_{L t}$, with:

$$
\begin{equation*}
\lambda=\frac{D-A}{R-A+\rho(D-R)}\left[\frac{e^{(r-g)(1-A)}-e^{-(r-g)(R-1)}}{(r-g)(D-A)}+\rho \frac{e^{-(r-g)(R-1)}-e^{-(r-g) H}}{(r-g)(D-A)}\right] \tag{E.17}
\end{equation*}
$$

If $\rho=1$, then we are back to the simpler $\lambda$ formula given by equation ( $E 12$ ). If $r-g=0$, then by construction $\lambda=1(\forall \rho \leq 1)$. With $r-g>0$, note that $\lambda^{\prime}(\rho)<0$, i.e. more generous pay-as-youpension systems lead to lower $\lambda$ factors. This simply reflects the fact that with $\mathrm{r}-\mathrm{g}>0$ pay-as-you-go pension systems have a lower rate of return than private wealth. This also implies that for given $s_{B}$ and $r-g$, less generous pensions (lower $\rho$ ) will actually lead to higher steady-state inheritance ratios $b_{y}{ }^{*}$ (see Table E5).
In the open economy case, both $g$ and $r$ are given, so $\rho$ has no further impact on $b_{y}{ }^{*}$. Of course lower $\rho$ leads to higher $\beta^{*}$ and lower $\mu^{*}$ (because of additional hump-shaped wealth accumulation), but in the open economy this has no impact on $r$. In effect the additional pension wealth is entirely invested in foreign assets, so there is no crowding out at all with other forms of wealth. Note however that the rise in $\beta^{*}$ also implies a rise in national
income, so the rise in $\overline{\mathrm{b}}_{\mathrm{y}}{ }^{*}$ will be less strong than the rise in $\mathrm{b}_{\mathrm{y}}{ }^{*}$. Calibration results (not reported here) show that the two effects almost exactly cancel out, so that a lower $\rho$ has virtually no impact on $\hat{b}_{y}$ *.

In the closed economy case, the rise in $\beta^{*}$ due to lower $\rho$ and the rise of pension wealth will lead to lower $r^{*}$, which in turn leads to lower $b_{y}{ }^{*}$. I.e. there will be partial crowding out between pension wealth and other forms of wealth. Calibration results (not reported here) show that this $r^{*}$ effect is somewhat larger than the $\lambda$ effect, so the overall effect of lower $\rho$ on steady-state $b_{y}{ }^{*}$ is slightly negative (but much smaller than in the dynastic model, where there was full crowding out). ${ }^{281}$

## E.6. Extension of the formulas to the case with population growth

So far, all theoretical results and formulas on inheritance flows were derived within the context of the simple stationary demographic structure introduced in section 5: everybody becomes adult at age A, has exactly one kid at age H , and dies at age D, so each cohort size is fixed (and normalized to 1), and that total (adult) population $N_{t}$ is also fixed (and is equal to adult life length: $\left.N_{t}=D-A\right)$. Note that all propositions also make the assumption that inheritance age $I=D-H$ was higher that adulthood age: $I=D-H>A$. This assumption is satisfied in modern societies (with $A=20$ and $H=30$, then $I=D-H>A$ as long as $D>50$ ), and allowed us to ignore children altogether (they never own any wealth, nor do they receive any income) and concentrate on the analysis of the age-wealth profile $\mathrm{w}_{\mathrm{t}}(\mathrm{a})$ within the adult population ( $a \in[A ; D]$ ). This assumption might however not hold in some ancient societies (e.g. if $A=20, H=30$ and $D=40$, then $I=D-H=10$ ). It can easily be relaxed, and all results and formulas can be extended to the case with children inheritors, with minor changes. ${ }^{282}$

Next, and most importantly, all propositions can also be generalized to a model with selfsustained (positive or negative) population growth. Generally speaking, the impact of population growth on steady-state inheritance flows is similar to the impact of productivity growth, and for the most part one simply needs to replace $g$ by $g+n$ (where $g$ is

[^174]productivity growth and $n$ is population growth) in the steady-state formulas. This is illustrated by Propositions 12-13 below.

Consider the following demographic structure. Everybody becomes adult at age $\mathrm{a}=\mathrm{A}$, has $1+\eta$ children at age $a=H>A$, and dies at age $D>H$. Everybody again inherits at age $I=D-$ $H>A$. The only difference with the demographic structure used so far is that we allow the (average) number of children to differ from 1, i.e. $\eta$ can now be positive or negative. Noting $f$ the fertily rate (average number of children per woman), we simply have: $1+\eta=f / 2$. Each cohort size $\mathrm{N}^{\mathrm{x}}$ now grows at rate n , and so does total adult population $\mathrm{N}_{\mathrm{t}} .^{283}$

$$
\begin{gather*}
N^{x}=e^{n x} \\
N_{t}(a)=e^{n(t-a)} \\
N_{t}=\int_{A \leq a \leq D} N_{t}(a) d a=e^{n t} \frac{e^{-n A}-e^{-n D}}{n} \\
\text { With: } e^{n H}=1+\eta=f / 2, \text { i.e. } n=\frac{\log (f / 2)}{H} \tag{E.18}
\end{gather*}
$$

Example: With a fertily rate $f=2.0$ children per woman, then $n=0$ : we are back to the case with zero population growth. A fertily rate $\mathrm{f}=2.2$ means that everybody has 1.1 children, i.e. the population rises by $10 \%$ every generation, so for generation length $\mathrm{H}=30$ this corresponds a population growth rate $n=0.3 \%$ per year. A fertily rate $f=3.0$ corresponds to $n=1.4 \%$. Conversely, a fertility rate $f=1.5$ corresponds to $n=-1.0 \%$.

Because we assume steady-state population growth, the mortality rate $m_{t}$ is stationary:

$$
\begin{equation*}
m_{t}=\frac{N_{t}(D)}{N_{t}}=m^{*}=m(n)=\frac{n}{e^{n(D-A)}-1} \tag{E.19}
\end{equation*}
$$

Note that $m^{\prime}(\mathrm{n})<0$ : in growing populations, dying cohorts are smaller in size than living cohorts, so the mortality rate is lower. If $n=0$, we are back to the case with zero population growth: $m^{*}=1 /(D-A)$. If $n>0, m(n)<1 /(D-A)$. If $n<0, m(n)>1 /(D-A)$.

The rest of the model is unchanged. We still assume a Cobb-Douglas production function $Y_{t}=F\left(K_{t}, H_{t}\right)=F\left(K_{t}, e^{g t} L_{t}\right)$ with exogenous productivity growth $g \geq 0$. With an exogenous

[^175]saving rate $s=\alpha s_{K}+(1-\alpha) s_{L}$, one simply needs to replace $g$ by $g+n$ in the Harrod-DomarSolow closed-economy formula for steady-state $\beta^{*}$ and $r^{*}$ :
\[

$$
\begin{aligned}
\beta^{*} & =\frac{s}{g+n} \\
r^{*}=\frac{\alpha}{\beta^{*}} & =\frac{\alpha(g+n)}{s}
\end{aligned}
$$
\]

In steady-state national income $\mathrm{Y}_{\mathrm{t}}$ and aggregate wealth $\mathrm{W}_{\mathrm{t}}$ grow at rate $\mathrm{g}+\mathrm{n}$. Per adult income $y_{t}=Y_{t} / N_{t}$ and per adult wealth $w_{t}=W_{t} / N_{t}$ grow at rate $g$. We are looking for a steadystate where the aggregate inheritance flow $B_{t}$ also grows at rate $g+n$, while per decedent inheritance $b_{t}=w_{t}(D)$ grows at rate $g$. We again need to solve for the steady-state agewealth profile $\mathrm{w}_{\mathrm{t}}(a)$. Note that because of population growth, average bequest left and average bequest received do not longer coincinde: at time $t$, decedents leave average bequest $b_{t}=w_{t}(D)=B_{t} / N_{t}(D)$, while successors receive average bequest $b_{t} / e^{n H}=B_{t} / N_{t}(I)$.

One can easily show that in the class saving case, the results obtained for $b_{w}{ }^{*}$ and $b_{y}{ }^{*}$ are wholly unaffected by the introduction of population growth:

## Proposition 12 (class saving model with population growth)

Assume pure class savings ( $s_{L}=0 \& s_{k}>0$ ) and population growth ( $n>0$ or $n<0$ ). As $t \rightarrow+\infty$, $\mu_{\mathrm{t}} \rightarrow \mu^{*}, b_{\mathrm{wt}} \rightarrow \mathrm{b}_{\mathrm{w}}{ }^{*}$ and $\mathrm{b}_{\mathrm{yt}} \rightarrow \mathrm{b}_{\mathrm{y}}{ }^{*}$. Steady-state ratios $\mu^{*}, b_{w}{ }^{*}$ and $b_{y}{ }^{*}$ are given by:
(1) The ratio $\mu^{*}$ between average wealth of decedents and average adult wealth depends solely on demographic parameters: $\mu^{*}=\mu(n)=\frac{e^{n(D-A)}-1}{n H}=\frac{1}{H m^{*}}$
(2) The inheritance flow-private wealth ratio $b_{w}{ }^{*}=\mu^{*} m^{*}$ and the estate multiplier $e^{*}=1 / b_{w}{ }^{*}$ depend solely on generation length $H: b_{w}{ }^{*}=\bar{b}_{w}=1 / H$ and $e^{*}=\bar{e}=H$
(3) The inheritance flow-national income ratio $b_{y}{ }^{*}=\mu^{*} m^{*} \beta^{*}$ depends solely on the aggregate wealth-income ratio $\beta^{*}$ and on generation length $H: \quad b_{y}{ }^{*}=\bar{b}_{y}=\beta^{*} / H$

Proof of Proposition 12. The steady-state cross-sectional age-profile $w_{t}(a)$ looks as follows. Since $s_{L}=0$, young individuals have zero wealth until the time they inherit. Now take the group of individuals with age $a>1$ at time $t$. They inherited a-l years ago, at time $s=t-a+l$. They received average bequests $b_{s} / e^{n H}=e^{-g(a-1)} b_{t} / e^{n H}$. But although they received smaller bequests, they saved a fraction $s_{K}=(g+n) / r^{*}$ of the corresponding return, so at time
$t$ their inherited wealth is now equal to: $w_{t}(a)=e^{(g+n)(a-1)} e^{-g(a-1)} b_{t} / e^{n H}=e^{n(a-D)} b_{t}$. So we have the following steady-state profile:

If $a \in\left[A, I\left[\right.\right.$, then $w_{t}(a)=0$
If $a \in[I, D]$, then $w_{t}(a)=e^{n(a-D)} b_{t}$

So with positive population growth $n>0$, the cross-sectional age-average wealth profile is now upward sloping after inheritance age: on average younger successors are poorer than older successors. However the cross-sectional age-aggregate wealth profile is still flat: younger successors are poorer, but they are more numerous, and both effects exactly compensate each other. That is, if we define $W_{t}(a)=N_{t}(a) W_{t}(a)$, we have:

If $a \in\left[A, I\left[\right.\right.$, then $W_{t}(a)=0$
If $a \in[I, D]$, then $W_{t}(a)=e^{n(t-D)} b_{t}=B_{t}$

It follows that aggregate wealth $W_{t}=(D-I) B_{t}=H B_{t}$, i.e. $b_{w}{ }^{*}=1 / H$ and $b_{y}{ }^{*}=\beta^{*} / H$.
Alternatively, we get the following formula for average wealth:

$$
w_{t}=\left[\int_{A \leq a \leq D} N_{t}(a) w_{t}(a) d a\right] / N_{t}=\frac{n H e^{-n D}}{e^{-n A}-e^{-n D}} b_{t}
$$

So we have:

$$
\begin{equation*}
\mu^{*}=\mu(n)=\frac{e^{n(D-A)}-1}{n H}=\frac{1}{H m^{*}} \tag{E.20}
\end{equation*}
$$

Note that $\mu^{*}>\bar{\mu}=(D-A) / H$ if $n>0$, and $\mu^{*}<\bar{\mu}$ if $n<0$. When population grows faster, the mortality rate $\mathrm{m}^{*}$ is lower, but the relative wealth of decedents $\mu^{*}$ is higher, so that the product $b_{w}{ }^{*}=\mu^{*} m^{*}=1 / H$ is unchanged.

## End of proof of Proposition 12.

Now consider the wealth-in-utility model. One can show that the formula for steady-state inheritance flows obtained under population stationarity is almost the same in the model with zero population growth (see Propositions 8-9). That is, one simply needs to replace $g$ by $\mathrm{g}+\mathrm{n}$ in the steady-state formula for $\mathrm{b}_{\mathrm{y}}{ }^{*}$, and to add an additional term to the $\lambda$ factor:

Proposition 13 (wealth-in-the-utility model with population growth).
As $t \rightarrow+\infty, \mu_{t} \rightarrow \mu^{*}=\mu(g, r), b_{w t} \rightarrow b_{w}{ }^{*}=\mu^{*} m^{*}$, and $b_{y t \rightarrow} \rightarrow b_{y}{ }^{*}=\mu^{*} m^{*} \beta^{*}=\frac{s_{\mathrm{B}} \lambda^{\prime}(1-\alpha) e^{(r-g-n) H}}{1-s_{B} e^{(r-g-n) H}}$
With: $\lambda^{\prime}=\lambda \frac{(D-A) N_{t}(I)}{N_{t}}=\lambda \frac{n(D-A) e^{-n l}}{e^{-n A}-e^{-n D}}$
And: $\lambda=\frac{e^{(r-g)(1-A)}-e^{-(r-g)(D-I)}}{(r-g)(D-A)}$

Proof of Proposition 13. Consider the inheriting cohort at time $t$, i.e. the cohort born at time $x=t-I$. We again note $\tilde{y}_{t}=\tilde{b}_{t}+\tilde{y}_{L t}$ the average lifetime resources received by this cohort, where $\tilde{\mathrm{b}}_{\mathrm{t}}$ is the average end-of-life capitalized value of their inheritance resources, and $\tilde{y}_{L t}$ is the average end-of-life capitalized value of their labor income resources.

We have:
$\tilde{b}_{t}=e^{r H} B_{t} / N_{t}(I)$.
$\tilde{y}_{L t}=e^{r H} \lambda(D-A)(1-\alpha) Y_{t} / N_{t}$
In the same way as in the zero population growth case, utility maximization implies that the average bequest $b_{t+H}$ left by cohort $x$ is equal to $a$ a fraction $s_{B}$ of their end-of-life capitalized lifetime resources $\tilde{y}_{t}$. So in aggregate terms we have:

$$
\begin{align*}
& B_{t+H}=s_{B} N_{t}(I)\left[e^{r H} B_{t} / N_{t}(I)+e^{r H} \lambda(D-A)(1-\alpha) Y_{t} / N_{t}\right] \\
& \text { I.e. } \quad B_{t+H}=s_{B} e^{r H}\left[B_{t}+\lambda^{\prime}(1-\alpha) Y_{t}\right] \\
& \text { With: } \lambda^{\prime}=\lambda \frac{(D-A) N_{t}(I)}{N_{t}} \tag{E.21}
\end{align*}
$$

Note that the additional term $\frac{(D-A) N_{t}(I)}{N_{t}}$ is simply the ratio between the size of the currently inheriting cohort $N_{t}(I)$ and average cohort size $N_{t} /(D-A)$. With zero population growth this ratio is equal to $100 \%$ and this additional term disappears. More generally, if $n$ is small, and if inheritance happens around mid-life, one can see that it will be close to 100\% (the first-order term disappears, in the same way as in the $\lambda$ formula).
Dividing both sides of equation (E21) by $Y_{t+H}=Y_{t} e^{(g+n) H}$, we get the following transition equation for the inheritance flow-national income ratio $b_{y t}=B_{t} / Y_{t}$ :

$$
b_{y t+H}=s_{\mathrm{B}} e^{(r-g-n) H}\left[b_{y t}+\lambda^{\prime}(1-\alpha)\right]
$$

Assuming $s_{B} e^{(r-g-n) H}<1$, we have a unique steady-state $b_{y}{ }^{*}=\frac{S_{B} \lambda^{\prime}(1-\alpha) e^{(r-g-n) H}}{1-S_{B} e^{(r-g-n) H}}$.
Higher population growth reduces the relative importance of inheritance, in the same way as higher productivity growth. Conversely, negative population growth raises the relative importance of inheritance. If $n$ is sufficientely negative, then $s_{B} e^{(r-g-n) H}>1$, i.e. we have an explositive path. Intuitively, in a society where individuals almost stop having children, the size of dying cohort becomes very large as compared to the size of the inheriting cohorts, and so does the inheritance flow as compared to national income.

## End of proof of Proposition 13.

## List of files

The folder www.jourdan.ens.fr/piketty/inheritance contains the following files:

1. Piketty2010WP.pdf = pdf file for the working paper "On the Long Run Evolution of Inheritance - France 1820-2050", PSE, 2010
2. Piketty2010DataAppendixPart1.pdf \& Piketty2010DataAppendixPart2.pdf $=$ pdf files for the present data appendix
3. Piketty2010DataAppendix.zip = zip file containing detailed tables, figures, data files and computer codes in excel and stata formats:

- MainTablesFigues.xls = excel file containing all tables and figures included in the working paper, with linked formulas to other excel files \& sheets
- AppendixTables(NationalAccountsData).xls = excel file containing all tables from appendix A, with linked formulas to other excel files \& sheets
- AppendixTables(EstateTaxData).xls = excel file containing all tables from appendix B, with linked formulas to other excel files \& sheets
- AppendixTables(DemoData).xls = excel file containing all tables from appendix C, with linked formulas to other excel files \& sheets
- AppendixTables(Simulations).xls = excel file containing all tables from appendix D, with linked formulas to other excel files \& sheets
- AppendixTables(SSFormulas).xls = excel file containing all tables from appendix E, with linked formulas to other excel files \& sheets
- AppendixFigures.xls = excel file containing supplementary figures drawn from appendix tables, with linked formulas to other excel files \& sheets
- AppendixDataFiles.zip: zip file containing a number of stata format data sets and do files used in the simulations (the exact list and description of these files is given in Appendix C3 and Appendix E6).

    ** I am grateful to seminar participants at the Paris School of Economics, Universitat Pompeu Fabra (Barcelona), the Massachussetts Institute of Technology, Harvard University, New York University, Boston University and the University of Chicago for helpful reactions. All comments are welcome (piketty@ens.fr).

[^2]:    ${ }^{1}$ It is critical to include both bequests (wealth transmitted at death) and gifts (wealth transmitted inter vivos) in our definition of inheritance, first because gifts have always represented a large fraction of total wealth transmission, and next because this fraction has changed a lot over time. Throughout the paper, the words "inheritance" or "bequest" or "estate" will refer to the sum of bequests and gifts, unless otherwise noted.

[^3]:    ${ }^{2}$ Whether one should use national or disposable income as denominator is a matter of perspective. If one assumes that government expenditures are useless, and that the rise of government during the $20^{\text {th }}$ century has limited the ability of private individuals to save, accumulate and transmit private wealth, then one should use disposable income. But to the extent that government expenditures are mostly useful (e.g. assuming that in the absence of public spending in health and education, then individuals would have to had to pay at least as much to buy similar services on the market), it seems more justified to use national income. One additional advantage of using national income is that it tends to be better measured. Disposable income can display large time-series and cross-country variations for purely definitional reasons. E.g. in France, disposable income would jump from $70 \%$ to about $80 \%$ of national income if one includes in-kind health transfers (such as insurance reimbursements), and to about $90 \%$ of national income if one includes all inkind transfers (education, housing, etc.). See Appendix A.

[^4]:    ${ }^{3}$ Here we simply report raw wealth shares from the 2007 SCF (see Kennickell (2009, Table 4)), with no correction whatsoever. Kennickell later compares the top wealth levels reported in the SCF with other sources (such as Forbes 500 rankings), and finds that the SCF understates top wealth shares.
    ${ }^{4}$ See Piketty, Postel-Vinay and Rosenthal (2006).
    ${ }^{5}$ See e.g. Atkinson (1983, p.176, table 7.4) for U.K. top wealth shares broken down by age groups.

[^5]:    ${ }^{6}$ See section 3.2 below.

[^6]:    ${ }^{7}$ See Atkinson and Piketty $(2007,2010)$ for the complete set of country studies, and Atkinson, Piketty and Saez (2010) for a recent survey. To a large extent, this project is a simple extension of Kuznets (1953) pioneering and innovative work. Kuznets was the first researcher to combine income tax return data with national income accounts data in order to compute top income shares series, using U.S. data over the 19131948 period. In a way, what we do in the present paper is also following Kuznets: we attempt to integrate national income and wealth accounts with income and estate tax data.
    ${ }^{8}$ Partial corrections were made for a number of countries, but there was no systematic attempt to develop an imputation method. One should be aware of the fact that for most countries (including France, the U.K. and the U.S.), our series measure the share of top reported incomes (rather than top economic incomes).
    ${ }^{9}$ Wolff and Zacharias (2009) attempt to combine income and wealth data from the Survey of consumer finances (SCF) in order to obtain more comprehensive measures of top capital income flows in the US during

[^7]:    the 1980s-1990s. As they rightly point out, it is not so much that the "working rich" have replaced "couponclipping rentiers", but rather that "the two groups now appear to co-habitate at the top end of the distribution".
    ${ }^{10}$ See Kopczuk and Saez (2004) for the U.S., Piketty, Postel-Vinay and Rosenthal (2006) for France, and Roine and Waldenstrom (2009) for Sweden. These studies follow the pioneering work by Lampman (1962) and Atkinson and Harrison (1978), who respectively use U.S. 1922-1956 estate tax tabulations and U.K. 1923-1972 estate tax tabulations in order to compute top wealth share series.
    ${ }^{11}$ Given the relatively low quality of available wealth data for the recent period, especially regarding top global wealth holders, one should be modest and cautious about this conclusion.
    ${ }^{12}$ One exception is Edlund and Kopczuk (2009), who use the fraction of women in top estate brackets as a proxy for the relative importance of inherited vs self-made wealth. This is a relatively indirect way to study inheritance, however, and it ought to be supplemented by direct measures.

[^8]:    ${ }^{13}$ E.g. Galor and Moav (2006) take as granted the "demise of capitalist class structure", but are not fully explicit about what they mean by this. It is unclear whether this is supposed to be an aggregate phenomenon (involving a general rise of labor income relatively to capital income and/or inheritance, as suggested by their informal discussion of the "rise in human capital") or a purely distributional phenomenon (involving a compression of the wealth distribution, for given aggregate wealth-income and inheritance-income ratios, as suggested by their theoretical model). De Long (2003) takes an explicitly long term perspective on inheritance and informally discusses the main effects at play. However his intuition according to which the rise of life expectancy per se should lead to a decline in the importance of inheritance relatively to labor income turns out to be wrong, as we show in this paper.
    ${ }^{14}$ See e.g. Kessler and Masson (1989), Gale and Scholz (1994), Gokhale et al (2001).
    ${ }^{15}$ See e.g. Castaneda, Dias-Gimenes and Rios-Rull (2003), DeNardi (2004), Nirei and Souma (2007), Benhabib and Bisin (2009), Benhabib and Zhu (2009), Fiaschi and Marsili (2009) and Zhu (2010). See Cagetti and De Nardi (2008) for a recent survey of this literature.

[^9]:    ${ }^{16}$ For standard references on the "estate multiplier" formula, see Foville (1893), Colson (1903) and Levasseur (1907). The approach was also largely used by British economists (see e.g. Giffen (1878)), though less frequently than in France, probably because French estate tax data was more universal and easily accessible, while the British could use the income flow data from the schedular income tax system. ${ }^{17}$ See e.g. Colson (1927), Danysz (1934) and Fouquet (1982).

[^10]:    ${ }^{18}$ See Mallet (1908), Séailles (1910), Strutt (1910), Mallet and Strutt (1915) and Stamp (1919). This other way to use estate tax data was followed by Lampan (1962), Atkinson and Harrison (1978), and more recent authors (see above). See also Shorrocks (1975).
    ${ }^{19}$ The accounting equation given in section 3 below $\left(e_{t}=W_{t} / B_{t}=1 / \mu_{t} m_{t}\right)$ is of course identical to the mortality multiplier formula, except that we use it the other way around: we use it to compute inheritance flows from the wealth stock, while it has generally been used to compute the wealth of living from decedents' wealth.
    ${ }^{20}$ See e.g. Brumberg and Modigliani (1954), Ando and Modigliani (1963) and Modigliani (1986).

[^11]:    ${ }^{21}$ In 2008, French national income $Y_{t}$ was about 1,700 billions $€$, aggregate private wealth $W_{t}$ was about 9,500 billions $€$, and adult population was about 47 millions, so $y_{\mathrm{t}} \approx 35,000 €$ and $\mathrm{w}_{\mathrm{t}} \approx 200,000 €$. The number of adult decedents was about 540,000 , so the mortality rate $m_{\mathrm{t}} \approx 1.2 \%$. Here we give round up numbers to simplify exposition. For $\mu_{\mathrm{t}}$ we actually report the gift-corrected ratio $\mu_{\mathrm{t}}{ }^{*}$ (see below), so "average inheritance

[^12]:    per decedent" corresponds to "total bequests and gifts divided by number of decedents". For complete computations and exact values, see Appendix A, Table A2, line 2008.
    ${ }^{22}$ See section 7 below.
    ${ }^{23}$ All detailed demographic series and references are given in Appendix C.

[^13]:    ${ }^{24}$ Throughout the paper, "adult" means "20-year-old and over". In practice, children wealth is small but positive (parents sometime die early). In our estimates, we do take into account children wealth, i.e. we add a (small) correcting factor to the $\mu_{\mathrm{t}}$ ratio in order to correct for the fact that the share of adult wealth in total wealth (both among the deceased and among the living) is slightly smaller than $100 \%$. See Appendix B2.
    ${ }^{25}$ See Appendix B2. We use the mortality rates differentials broken down by wealth quartiles and age groups estimated by Attanasio and Hoynes (2000). If anything, we probably over-estimate differential mortality a little bit. Consequently, our resulting $\mu_{t}$ series and inheritance series are probably (slightly) under-estimated.
    ${ }^{26}$ The fact that we use estate tax data to compute our economic inheritance flow series does not affect the independence between the economic and fiscal series, because for the economic flow computation we only use the relative age-wealth profile observed in estate tax returns (not the absolute levels).
    ${ }^{27}$ Whether one starts from wealth-of-the-living or wealth-at-death raw age-wealth profiles, one needs to use differential mortality factors in one way or another in order to compute the $\mu_{\mathrm{t}}$ ratio.

[^14]:    ${ }^{28}$ See Appendix B2 and section 4.3 below.

[^15]:    ${ }^{29}$ All national accounts series, references and computations are described in a detailed manner in Appendix A. Here we simply present the main data sources and conceptual issues.
    ${ }^{30}$ In particular, the factor income decompositions (wages, profits, rents, business income, etc.) series released by Villa (1994) rely primarily on the original series constructed by Dugé de Bernonville (1933-1939), who described very precisely all his raw data sources and computations. For more detailed technical descriptions of the Dugé and Villa series, see Piketty (2001, pp.693-720).

[^16]:    ${ }^{31}$ We used the $19^{\text {th }}$ century series due to Bourguignon and Lévy-Leboyer (1985) and Toutain (1987).
    ${ }^{32}$ The concepts and methods used in Insee-Banque de France balance sheets are broadly similar to the flows-of-funds and tangible-assets series released by the U.S. Federal Reserve and Bureau of Commerce.
    ${ }^{33}$ More details on these issues are provided in Appendix A4.

[^17]:    ${ }^{34}$ For a more detailed technical analysis of the series, see Appendix A3 and A4.
    ${ }^{35}$ All "real" growth rates (either for national income or for private wealth) and "real" rates or return referred to in this paper are defined relatively to consumer price inflation. Any CPI mismeasurement would translate into similar changes for the various rates without affecting the differentials and the ratios.
    ${ }^{36}$ Net foreign assets gradually rose from about $2 \%$ of private wealth in 1820 to about $15 \%$ around 19001910, i.e. from about $10 \%$ of national income to about $100 \%$ of national income. See Appendix A, Table A16.

[^18]:    ${ }^{37}$ In the benchmark estimates reported on Table 1, private saving flows are defined as the sum of personal savings and net corporate retained earnings (our preferred definition). If we instead use personal saving flows, we find a lower $g_{w s}(2.0 \%)$ and a modest positive $q$ effect $(+0.4 \%)$. Taken literally, this would mean that asset prices are currently about $40 \%$ higher than what they were in 1913, but that if we deduct the cumulated value of corporate retained earnings, then they are actually $30 \%$ smaller. Within our accounting framework, retained earnings account for about a third of total real capital gains during the 1949-2009 period, which seems reasonable. For detailed results, see Appendix A5, Table A19, from which Table 1 is extracted.

[^19]:    ${ }^{38}$ Here we piece together the following data sources: for the late $19^{\text {th }}$ century and early $20^{\text {th }}$ century, we use the private wealth and national income estimates of the authors of the time (see e.g. Giffen (1878) and Bowley (1920)); for the period going from the 1920s to the 1970s, we use the series reported by Atkinson and Harrison (1978); for the 1990s-2000s we use the official personal wealth series released on hmrc.gov.uk. See also Solomou and Weale (1997, p.316), whose 1920-1995 UK wealth-income ratio series display a similar U-shaped pattern (from $600 \%$ in the interwar down to less than $400 \%$ in the 1950 s -1970s, up to $500 \%-600 \%$ in the 1980s-1990s).
    ${ }^{39}$ Here we use for the post-1952 period the net worth series (household and non-profit sectors) released by the Federal Reserve (see e.g. Statistical Abstract of the U.S. 2010, Table 706), and for the pre-1952 period the personal wealth series computed by Kopczuk and Saez (2004, Table A) and Wolff (1989). .
    ${ }^{40}$ All estate tax series, references and computations are described in a detailed manner in Appendix B. Here we simply present the main data sources and conceptual issues.

[^20]:    ${ }^{41}$ This is reflected in the official name of the tax, which since 1791 has always been "droits d'enregistrement" (more specifically, "droits d'enregistrement sur les mutations à titre gratuity" (DMTG)), rather than "impôt sur les successions et les donations". In the U.S., the estate tax is simply called the "estate tax".
    ${ }^{42}$ See Appendix A, Table A9, col. (15). This low aggregate effective tax rate reflects the fact that top rates only apply to relatively high wealth levels (e.g. the top $40 \%$ marginal rate currently applies to per children, per parent bequests above 1.8 millions euros), and the fact that tax exempt assets and tax rebates for inter vivos gifts have become increasingly important over time. See Appendix B for more details.

[^21]:    ${ }^{43}$ See Piketty, Postel-Vinay and Rosenthal (2006).
    ${ }^{44}$ The spouse share has always been about $10 \%$ of the aggregate estate flow, vs. $70 \%$ for children and $20 \%$ for non-spouse, non-children heirs, typically siblings and nephews/nieces (see Appendix C2). It is unclear why one should exclude the spouse share and not the latter. In any case, this would make little difference.

[^22]:    ${ }^{45}$ Gender-based wealth inequality is an important issue. On average, however, women have been almost as rich as men in France ever since the early $19^{\text {th }}$ century (with aggregate women-men wealth ratios usually in the $80 \%-90 \%$ range; this is largely due to the gender neutrality of the 1804 Civil Code; see Piketty et al (2006)). So the aggregate consequences of ignoring gender issues cannot be very large.
    ${ }^{46}$ Parental transfers to non-adult children and educational investments raise complicated empirical and conceptual issues, however. One would need to look at the financing of education as a whole.

[^23]:    ${ }^{47}$ We know little as to why inter vivos gifts were so high in the early $19^{\text {th }}$ century. This seems to correspond to the fact that dowries (i.e. large inter-vivos gifts at the time of wedding) were more common at that time.
    ${ }^{48}$ The raw profiles reported on Table 2 do not take into account differential mortality. If one were to use them to compute $\mu_{\mathrm{t}}$ ratios without making any correction, then one would find substantially bigger for values for $\mu_{\mathrm{t}}$ than those reported on Figure 8, e.g. 171\% instead of 135\% for 1912. Estimated age-wealth profiles for the living (i.e. after taking into account the differential mortality correction) are also steeply increasing up until the very old. See Appendix B2, Tables B3-B5 for detailed computations and results.
    ${ }_{5}^{49}$ See Piketty, Postel-Vinay and Rosenthal (2006).
    ${ }^{50}$ The differential-mortality-corrected profiles look even more hump-shaped (see Appendix B2).

[^24]:    ${ }^{51}$ Differential-mortality-corrected profiles are basically flat above age 50 (see Appendix B2). Using the 1998 and 2004 Insee wealth surveys, we find age-wealth profiles which are slightly declining after age 50 (the 70-to- 79 and 80 -to- 89 -year-old own about $90 \%$ of the 50 -to- 59 -year-old level). However this seems to be largely due to top-wealth under-reporting in surveys. Using wealth tax data (see Zucman (2008, p.68)), we find that the fraction of the 70 -to- 79 and 80 -to-89-year-old subject to the wealth tax (i.e. with wealth above 1 million $€$ ) is around $200 \%-250 \%$ of the corresponding fraction for the 50 -to-59-year-old (average taxpayers wealth is similar for all age groups). This steeply rising profile does not show up at all in wealth surveys, and might also be under-estimated in estate tax data (e.g. because the elderly hold more estate-tax-exempt assets).
    ${ }^{52}$ However the upward trend in gifts clearly started before new tax incentives were put in place in the late 1990s and 2000s, so it is hard to identify the the tax effect per se. For additional details, see Appendix B.

[^25]:    ${ }^{53}$ See Appendix C, Table C8. The slight decline in average age of heirs plotted on Figure 7 for the post-2040 period corresponds to another effect, namely a slight projected rise in average age at parenthood.
    ${ }^{54}$ According to on-line IRS data, the U.S. gift-bequest ratio is about $20 \%$ in 2008 ( 45 billions $\$$ in gifts and 230 billions $\$$ in bequests were reported to the IRS). Unfortunately, the bequest data relates to less than $2 \%$ of U.S. decedents (less than 40,000 decedents, out of a total of 2.5 millions), and we do not really know what fraction of gifts were actually reported to the IRS. On-line IRS tables also indicate steeply rising age-wealth-at-death profiles. This is consistent with the findings of Kopczuk (2007) and Kopczuk and Luton (2007).

[^26]:    ${ }^{55}$ All results can be extended to the case with a non-stationary population $N_{t}$ growing at a fixed rate $n$ (generally by replacing $g$ by $\mathrm{g}+\mathrm{n}$ in the formulas and results). Below we also relax the deterministic mortality assumption and introduce demographic noise, i.e. the fact that different individuals die at different ages (or have children at different ages), and therefore that different individuals inherit at different ages.

[^27]:    ${ }^{56}$ E.g. with credit constraints high inheritance flows can have a negative impact on growth-inducing investments (high-inheritance low-talent agents cannot easily lend money to low-inheritance high-talent agents). So high inheritance could lead to lower growth, which itself tends to reinforce high inheritance, as we see below. This two-way process can naturally generate multiple growth paths (with a high inheritance, low mobility, low growth path, and conversely). See Piketty (1997) for a similar steady-state multiplicity.
    ${ }^{57}$ Below we also consider the open economy case. See Appendix E for the corresponding equations.

[^28]:    ${ }^{58}$ All results below can easily be extended to CES production functions of the form $F(K, H)=\left[a K^{(v-1) / v}+(1-a)\right.$ $\left.H^{(v-1) / r}\right]^{V(\gamma-1)}$, where $\gamma$ is the constant elasticity of substitution between $K$ and $H \quad(\gamma=1$ corresponds to CobbDouglas, $y=0$ to putty-clay, and $y=\infty$ to a linear production function). In competitive equilibrium the capital share $\alpha$ is then given by $\alpha=Y_{k} / Y=r \beta=a \beta^{1-1 / V}$. I.e. the capital share $\alpha$ is an increasing function of the wealthincome ratio $\beta$ if and only if $\gamma>1$. The fact that capital shares were slightly below normal levels in historical periods when the wealth-income ratio was below normal levels (e.g. in the 1950s) tends to suggest that $\gamma$ is somewhat bigger than 1 . However the assumption of competitive factor markets is quite heroic, especially during those periods (e.g. rent control and other policies influencing factor prices certainly played a big role at mid- $20^{\text {th }}$ century), and so is this inference process. See Appendix A for detailed factor shares series.

[^29]:    ${ }^{59}$ We will make this clear in the context of each specific saving model as we go along.
    ${ }^{60}$ In simulations we use observed, non-flat age-labor income profiles. In France, the current profile $\mathrm{y}_{\mathrm{Lt}}(\mathrm{a})$ is moderately upward sloping: the average labor income of adults aged 20 -to- 29 and 30 -to- 39 is about $70 \%$ $80 \%$ of the average labor income of those aged 40 -to- 49 and 50 -to-59. See Appendix D, Table D4.
    ${ }^{61}$ In a world with $\mathrm{r}>\mathrm{g}$, it is unclear why people would want to have pay-as-you-go pension systems (whose internal rate of return is by definition equal to g ). In order to do a proper welfare analysis, one would need to introduce into the model the reasons why pay-as-you-go systems were introduced in the first place (and why they remain popular in most developed countries), i.e. uninsurable uncertainty about the rate of return on private wealth r . This is in turn would have an impact on the welfare analysis of inheritance and on the structure of optimal taxes. We leave these difficult normative issues to future research.
    ${ }^{62}$ In what follows we often omit to specify that labor income y yt actually refers to "augmented" labor income.

[^30]:    ${ }^{63}$ That is, the average (augmented) labor income of adults aged 60-to-69, 70-to-79 and 80-and-over is about $70 \%-80 \%$ of the average labor income of those aged $50-$ to- 59 . See Appendix D, Table D4. In principle, with $A=20, R=60, D=80$, the pension tax rate should be $T_{\rho}=33 \%$ for $\rho=100 \%$ and $T_{\rho}=26 \%$ for $\rho=70 \%$. In practice, the French pension tax rate is a bit smaller (it is closer to $20 \%$ ), thanks to the fact that retired cohorts are somewhat smaller than working cohorts (i.e. population growth n is small but $>0$ ).
    ${ }^{64}$ For simplicity, here we ignore differential mortality (i.e. we implicitly assume uniform mortality rates for the poor and the rich). Of course we do take into account differential mortality in the simulations. In effect, this simply introduces a uniform downward correction factor on $b_{t}$. See Appendix B, section B2.

[^31]:    ${ }^{65}$ I.e. we assume $s_{t}(a)=s_{L} y_{L t}(a)+s_{K} r_{t} w_{t}(a)$ (with $s_{t}(a)=$ average savings of a-year-old individuals).
    ${ }^{66}$ One possible micro rationale for class saving behaviour is the dynastic model (see below). The more traditional, Kaldor-Pasinetti-type justification involves income effects: zero-wealth workers have wages below or around subsistence consumption and save little or not at all; while high-wealth capitalists are far above subsistence and save a large fraction of their capital income. One needs however to assume that the subsistence consumption level grows at rate g (maybe because of reference group effects). Our formulation for the general case is closer to Kaldor (1966) than to Pasinetti (1962), as the different savings propensities attach to types of income rather than to classes of people (i.e. once workers have started accumulated wealth from their labor income, their saving rate out of capital income is the same as the capitalists' saving rate; Kaldor's justification for this is corporate savings; but this is not really a micro founded explanation).
    ${ }^{67}$ See section 6 below and Antonin (2009) for recent estimates using French expenditure surveys.
    ${ }^{68}$ The flat saving rates that we assume here could come from any micro model, and do not need to be the same for all individuals. Because of linearity, all results below hold for any distribution of savings rates $\mathrm{s}_{\mathrm{Lti}}$ and $s_{\text {Kti }}$ (with both permanent intra-cohort heterogeneity and idiosyncratic within-lifetime shocks), as long as average savings rates $s_{L}$ and $s_{K}$ are the same for all age groups. More generally, all results obtained under the exogenous savings model also hold for any distribution of labor income $y_{\text {Lti }}$ and rate of return $\mathrm{r}_{\mathrm{ti}}$, as long as age-level averages are the same. The exact structure of shocks matters for the steady-state wealth distribution, but has no impact on steady-state aggregate ratios.
    ${ }^{69}$ This simply comes from the wealth accumulation equation $d W_{t} / d t=s Y_{t}$, i.e. $d \beta_{t} / d t=s-g \beta_{t}=0$ iff $\beta^{*}=s / g$. If population $N_{t}$ grows at rate $n>0$ (or $n<0$ ), then one simply needs to replace $g$ by $g+n$.

[^32]:    ${ }^{70}$ The formula $\beta^{*}=s / g$ was first derived by Harrod (1939) and Domar (1947) using fixed-coefficient production functions, in which case $\beta^{*}$ is entirely given by technology, hence the knife-edge growth conclusion (Harrod emphasized the inherent instability of the growth process; Domar stressed the possibility that $\beta^{*}$ and s can adjust in case the natural growth rate $g+n$ differs from $s / \beta^{*}$ ). The classic derivation of the formula with a production function $\mathrm{Y}=\mathrm{F}(\mathrm{K}, \mathrm{L})$ involving capital-labor substitution, thereby making balanced growth path possible, is due to Solow (1956). Authors of the time had limited national accounts at their disposal to estimate the parameters of the formula. In numerical illustrations they typically took $\beta^{*}=400 \%, g=2 \%, s=8 \%$.
    ${ }^{71}$ Note also that in micro founded models $\alpha<s$ and $r^{*}<g$ lead to dynamic inconsistencies: the present value of future resources is infinite, so agents should be willing to borrow, not to save. See the dynastic model below.

[^33]:    ${ }^{72}$ In section 7 below, we translate these results expressed in cross-sectional macroeconomic flows into results expressed in longitudinal lifetime resources.

[^34]:    ${ }^{73}$ If $A \leq a \leq 1-d$, then nobody has inherited, so $w_{t}(a)=0$. If $I-d \leq a \leq I+d$, then a fraction $(a-I+d) / 2 d$ has already inherited, and for those individuals the growth and capitalization effects again cancel each other, so that $w_{t}(a)$ is a linear fraction of age: $w_{t}(a)=(a-I+d) \bar{w}_{t} / 2 d$. If $a \geq I+d$, then everybody has inherited, so the age-wealth profile is flat: $w_{t}(a)=\bar{w}_{t}$. Average wealth $w_{t}=\left[2 d \bar{w}_{t} / 2+(D-I-d) \bar{w}_{t}\right] /(D-A)=(D-I) \bar{w}_{t} /(D-A)$ remains the same as before, and so do all other results of proposition 2.

[^35]:    ${ }^{74}$ For $g-s_{k} r^{*}$ small, $\mu(g) \approx \bar{\mu}\left[1-\left(g-s_{k} r^{*}\right)(D-A-H) / 2\right]$.

[^36]:    ${ }^{75}$ See Appendix E, Figures E1-E2. For a given saving rate s, steady-state $\beta^{*}$ (and not only $\mu^{*}$ ) rises as $g$ decreases, which also pushes towards higher $b_{y}{ }^{*}$. If $s \rightarrow 0$ as $g \rightarrow 0$, so as to keep $\beta^{*}=s / g$ and $r^{*}=\alpha / \beta^{*}$ constant, then in effect $\mathrm{g} / \mathrm{r}^{*} \rightarrow 0$ as $\mathrm{g} \rightarrow 0$, i.e. with low growth the capitalization effect is infinitely large as compared to the growth effect. The extreme case $g=0$ is indeterminate in the exogenous savings model: if $g=0$ and $s>0$, then as $t \rightarrow+\infty, \beta_{t} \rightarrow+\infty$ and $r_{t} \rightarrow 0$; if $g=0$ and $s=0$, then $\beta^{*}$ and $r^{*}$ are entirely determined by initial conditions; in both cases our key result still holds: $\mu_{\mathrm{t}} \rightarrow \bar{\mu}$ as $t \rightarrow+\infty$.
    ${ }^{76}$ See Appendix E, Table E1 for detailed computations using formulas (5.6)-(5.7).

[^37]:    ${ }^{77}$ Of course the other part of the explanation is that $\beta_{\mathrm{t}}$ was much smaller than $600 \%$ at that time. Here we report the findings obtained for $b_{y}{ }^{*}$ under the assumption of a fixed $\beta^{*}=600 \%$, so as to isolate the effect going through age-wealth profiles and the resulting $\mu^{*}$ ratio.
    ${ }^{78}$ See Appendix E, Table E1. In Appendix E we provide a closed-form formula for $\mu(\mathrm{g}, \mathrm{\rho})$ extending the above formula and show that our key result still holds: for all $\rho \leq 1, \mu(\mathrm{~g}, \rho) \rightarrow \bar{\mu}$ as $\mathrm{g} \rightarrow 0$.

[^38]:    ${ }^{79}$ See Appendix E, Table E2 for detailed computations using the $\mu(\mathrm{g}, \mathrm{r})$ formula.

[^39]:    ${ }^{80}$ This follows directly from the first-order condition describing the optimal consumption path: $\mathrm{dc}_{\mathrm{C}} / \mathrm{dt}=(\mathrm{r}-\theta) \mathrm{c}_{/} / \sigma$ i.e. utility-maximizing agents want their consumption path to grow at rate $\mathrm{g}_{\mathrm{c}}=(\mathrm{r}-\theta) / \sigma$. This is a steady-state iff $g_{81}=$ g, i.e. $r r^{*}=\theta+\sigma$ g. If $r>r^{*}$ they accumulate indefinitely, and if $r<r^{*}$ they borrow indefinitely.
    Since $\sigma$ is typically $>1$, one can be sure that $r^{\star}=\theta+\sigma g>g$. In the (unplausible) case where $\sigma<1$, then in theory one could have $r^{*}<g$. However this would then violate the transversality condition, so this would not be a steady-state (the net present value of future income flows would be infinite, and everybody would like to borrow infinite amounts against future resources, thereby pushing $r$ upwards).
    ${ }_{82}$ The fact that the equilibrium, aggregate rate of return on assets $\mathrm{r}^{*}(\mathrm{~g})$ is always higher than g and an increasing function of $g$ in standard models ( $\mathrm{r}^{*}=\mathrm{ag} / \mathrm{s}$ with exogenous savings, $\mathrm{r}^{*}=\theta+\sigma \mathrm{g}$ with dynastic savings) is well known to macroeconomists (see e.g. Baker et al (2005) for an application to pension projections).
    ${ }^{83}$ See e.g. Bertola et al (2006, chapter 3). Note however that the steady-state equation $r^{*}=\theta+\sigma g$ only applies to the case of perfect capital markets, and in particular in the absence of uninsurable idiosyncratic shocks. So in order to keep the model simple we need to assume that all generations of a given dynasty $i$ have the same labor productivity parameter $\bar{y}_{\mathrm{Lti}}=\mathrm{y}_{\mathrm{Lt}} / y_{\mathrm{Lt}}$, i.e. the same relative position in the distribution of labor income of their time. In the absence of any other shock, all generations of a given dynasty $i$ also have the same relative position $\bar{b}_{t i}=b_{t i} / b_{t}$ in the wealth-at-death distribution of their time. Relative positions for labor income and inherited wealth do not need to be perfectly correlated across dynasties: any stationary joint

[^40]:    distribution $G\left(\bar{y}_{L t i}, \bar{b}_{t i}\right)$ is a steady-state of the dynastic model, as long as the aggregate $\beta_{t}=w_{t} / y_{t}$ is equal to $\beta^{*}$. Shocks on dynastic productivity parameters would generate precautionary savings (i.e. high productivity parents would accumulate extra wealth in order to protect their children against the risk of having a low productivity). This would lead to higher aggregate wealth accumulation and push steady-state $r<r^{*}$. This would complicate the resolution of the model, without offering substantial additional insights.
    ${ }^{84}$ In particular, there is uncertainty about time of parental death, future parental wealth, etc. so banks may not like lending against future inheritance. Also parents may not like to see their children borrow against their own death, and can threaten to disinherit them.

[^41]:    ${ }^{85}$ See Appendix E for numerical illustrations and Figure E4 for the steady-state age-wealth profile.

[^42]:    ${ }^{86}$ This is larger than the estimated share of annuitized wealth in French aggregate private wealth, which appears to be less than $5 \%$ (mostly through the annuitized fraction of life insurance assets). See Appendix A.

[^43]:    ${ }^{87}$ See Appendix E, Tables E3-E4 and Figures E5-E8 for detailed computations and age-wealth profiles.
    ${ }^{88}$ We also assume that young workers cannot borrow from future inheritance, and that expected inheritance does not reduce lifecycle saving. This is more realistic than full borrowing, but probably too extreme.
    ${ }^{89}$ According to Blau (2009), empirical estimates of the crowding-out effect of pension wealth on total household wealth are much closer to zero than to -1. From a different angle, Poterba (2001) finds that there seems to be little effect of demographic changes and retirement patterns on observed asset returns.
    ${ }^{90}$ For national accounts based series on capital and labor tax rates $\mathrm{T}_{\mathrm{K}}$ and $\mathrm{T}_{\mathrm{L}}$ in France, see Appendix A. With taxes, the dynastic steady-state conditions are $\left(1-T_{K}\right) r^{*}=\theta+\sigma g$, and $\beta^{*}=\alpha / r^{*}=\left(1-T_{K}\right) \alpha /(\theta+\sigma g)$.

[^44]:    ${ }^{91}$ See e.g. Dynan, Skinner and Zeldes (2002) for a calibrated model illustrating how plausible uncertainty about end of life health spendings can generate substantial savings and wealth accumulation
    ${ }^{92}$ See e.g. Carroll (2000), who argues that this wealth-loving model is the best explanation as to why saving rates increase so much with the level of lifetime income. See also Dynan et al (2004) and Kpoczuk (2007).
    ${ }^{93}$ See Kopczuk and Lupton (2007).

[^45]:    ${ }^{94}$ This formula applies to the inheritance-domestic income ratio; the formula for the inheritance-national income ratio is more complicated. See Appendix E1. The factor $\lambda$ corrects for the differences between the lifetime profile of labor income and inheritance flows, and is typically close to 1 . See section 7 below.

[^46]:    ${ }^{95}$ Agents in this model do not care directly about the welfare of the next generation (but simply about their end-of-life wealth), so we do not need to assume any longer that all generations of a given dynasty i have the same labor parameter. Any shock structure will do, both for the distribution of labor income $y_{\mathrm{Li}}$ and of preference parameters $\mathrm{s}_{\mathrm{Bi}}$. By linearity, the aggregate steady-state only depends on the average $\mathrm{s}_{\mathrm{B}}$.
    ${ }^{96}$ See Appendix E, Tables E5-E11 for detailed results. Here we report partial results from Table E11 (closed economy case) and Table E7 (open economy case).

[^47]:    ${ }^{97}$ E.g. according to Barro (2009, Table 1), the average real rate of return on stocks has been as large as $7.5 \%$ over the 1880-2005 period, vs. 1.0\% for bonds (averages over 11 Oecd countries).
    ${ }^{98}$ Thanks to linear savings, and because we focus on age-level averages, we do not need to assume that all individuals get the same return: we are just assuming that average returns are the same for all age groups.
    ${ }^{99}$ The full transition equations, and detailed simulation results, are given in Appendix D.

[^48]:    ${ }^{100}$ See section 3.2 above and Appendix A5.

[^49]:    ${ }^{101}$ Using Insee household budget surveys for 1978, 1984, 1989, 1994, 2000 and 2006, one finds aggregate age-saving rates profiles that are rising somewhat until age 40-49, and almost flat above age 40-49: sligltly declining in 1978-1984-1989, flat in 1994-2000, slightly rising in 2006. In any case, these variations across age groups are always very small as compared to variations over permanent income quartiles. To the extent that wealth and capital income are adequately measured in such surveys, average savings rates also seem to vary little with respect to factor income shares. See Antonin (2009).
    102 Inheritance taxes are included, but have always been a small fraction of the total capital taxes, which mostly consist of flow taxes such as the corporate tax, personal capital income taxes, and housing taxes. See Appendix A, Tables A9-A11 for detailed series. There are approximate estimates, based on simplifying assumptions (especially regarding product taxes incidence). But the orders of magnitude seem to be right.

[^50]:    ${ }^{103}$ The capital share that has been approximately constant since the late 1980s, but is significantly larger than the level observed in the late 1970s-early 1980s.

[^51]:    ${ }^{104} \lambda=\left[e^{(r-g)(I-A)}-e^{(r-g)(I-D)}\right] /(r-g)(D-A)=1+(r-g)(2 I-A-D)$. With I=(A+D)/2, the first-order term disappears.
    ${ }^{105}$ See Appendix E, Table E5 for illustrative computations using the $\lambda$ formula.

[^52]:    ${ }^{106}$ See Appendix D, Tables D7-D8 for detailed simulation results.
    ${ }^{107}$ See Appendix D, Table D7. Values are expressed in 2009 euros. As far as the shares are concerned, it is of course irrelevant at what age we capitalize lifetime resources (as long as we use the same age for inheritance and labor resources, and a common rate of return).

[^53]:    ${ }^{108}$ See Appendix A, Table A11, col.(11). Here we exclude pension-related payroll taxes from labor income taxes (otherwise the aggregate labor tax rate would exceed $50 \%$, see col.(9)). This follows from the fact that we treat pensions as replacement income, i.e. as part of (augmented) labor income.
    109 See Appendix A, Table A9, col.(15). Inheritance taxes were included in capital income flow taxes $\mathrm{T}_{\mathrm{K}}$, which can be questioned. Given their low level, however, a direct imputation method would not make a big difference to our $\alpha^{{ }^{*}}$ and $\psi^{*}$ estimates. For a discussion of tax incidence issues, see Appendix A2.
    ${ }^{110}$ One might argue that the rise of taxes allowed for the rise of government services (e.g. education, health), and that this should be added to income. However these services are generally open to everybody, irrespective of whether one lives off labor income or inheritance. So as a first approximation $\alpha^{x_{*}}$ and $\Psi^{x}$ appear to be consistent measures of the aggregate share of inheritance in disposable lifetime resources.

[^54]:    ${ }^{111}$ See Appendix D, Table D8 for detailed simulation results.
    ${ }^{112}$ For a detailed analysis of historical changes in wealth concentration in France, see Piketty et al (2006).

[^55]:    ${ }^{113}$ Alternatively one can replace $b_{y} / \beta$ by $b_{w}\left(=B_{t} / W_{t}\right)$ in equations (7.6)-(7.7).

[^56]:    ${ }^{114}$ See Appendix E, Table E12 for illustrative computations using these formulas.

[^57]:    ${ }^{115}$ See Appendix D5, Table D9 for detailed results.

[^58]:    ${ }^{116}$ In addition to the estimate of the 1962 inheritance flow, both Kotlikoff-Summers and Modigliani used data on age-income and consumption profiles in the U.S. during the 1950s-1970s. Both sides were essentially applying different definitions to the same raw data (with a few differences, generally reinforcing each side).
    ${ }_{117}$ Using a 1975 French wealth survey, Kessler and Masson (1989) also find $\varphi_{t}{ }^{\mathrm{M}}$ around $40 \%$.
    ${ }^{118}$ E.g. Gokhale et al (2001) simulate the transmission of inequality via bequests by assuming inheritance flows around $6 \%$ of aggregate labor income and $1 \%$ of aggregate wealth, which seems very small to us. These flow ratios are taken from Auerbarch et al (1995, p.25). They are based upon relatively ancient agewealth profiles (taken from 1962 and 1983 SCF) and seem to wholly ignore inter vivos gifts.
    ${ }^{119}$ See Wolff (2002) for an attempt to use retrospective information on bequests and gifts reported in the 1989-1998 SCF (with no upward correction). We tried to use the retrospective questionnaires of the French wealth surveys conducted in 1992, 1998 and 2004, but found that self-reported bequest and gift flows were less than $50 \%$ of the fiscal flows (a lower bound of the true economic flows, given tax exempt assets). This is not due to imperfect recall: we also found this low ratio by comparing self-reported and fiscal flows for the past few years before each survey. We see no reason why reporting rates should be higher in similar wealth surveys in other countries, such as the SCF in the US. Reporting rates might also be biased, e.g. people who have consumed most of their inherited wealth might be particularly reluctant to report wealth transfers.

[^59]:    ${ }^{120}$ See e.g. Calvet, Campbell and Sodini (2009).

[^60]:    * Professor of Economics at the Paris School of Economics (PSE) \& Directeur d'études at the Ecole des Hautes Etudes en Sciences Sociales (EHESS)

[^61]:    ${ }^{1}$ The old franc was replaced by the new franc on January $1^{\text {st }} 1960$ ( 1 new franc $=100$ old francs), and the new franc was replaced by the euro on January $1^{\text {st }} 2002$ ( 1 euro $=6.55957$ new francs). In order to convert

[^62]:    1949-2001 current currency values into what we call current euros, we simply divided 1960-2001 new francs values by 6.55957, and 1949-1959 old francs values by 655.957. Current prices national accounts series released by Insee adopt the same monetary convention.
    ${ }^{2}$ See section A3 below for the corresponding equations and decompositions, using standard ESA 1995 definitions. All raw series and computations are provided in the appendix excel file.
    ${ }^{3}$ We downloaded the complete set of recently released Insee retrospective 1949-2008 national income accounts series on www.insee.fr on 15/09/2009. We used Insee tables 3.101 to 3.601 and the "tableaux économiques d'ensemble". It is preferable to use these Insee tables rather than the series released by international data collectors such as Oecd, Eurostat or the Imf, because Insee tables are more detailed and cover longer time spans. The estimates for 2007-2008 are likely to be slightly revised by Insee in the near future. For 2009-2010 we upgraded the 2008 values using the latest growth projection figures available (we assumed a nominal growth rate equal to $-2.0 \%$ for 2009 and $0.0 \%$ for 2010). Official French national accounts have been established and released by Insee since 1949, and currently follow the "Base 2000" (B2000) methodology (all retrospective series were recently retropolated using B2000 concepts), which is the French version of ESA 1995 (European System of Accounts) and SNA 1993 (UN System of National Accounts). In what follows we often refer to the ESA 1995 classification codes (the ESA 1995 manual is available on-line: http://circa.europa.eu/irc/dsis/nfaccount/info/data/ESA95/en/esa95en.htm).
    ${ }^{4}$ See section A3 below for more details on the way we used the Villa (1994) series. For additional details on alternative historical national accounts series in France, see Piketty (2001, pp.693-720).
    ${ }^{5}$ All decennial averages reported on Table A2 (and on subsequent decennial tables) were computed in this way, with the exception of the 1910 decennial average, which corresponds to an arithmetic average over years 1910-1913 rather than 1910-1919 (the earlier and later parts of the 1910-1919 decade are so different that it does not make much sense to compute a decennial average; in addition it is useful to have a 19101913, pre-World War 1 reference point).
    ${ }^{6}$ The raw averages computed from the series provided by Bourguignon and Lévy-Leboyer (1985, pp.318322) are slightly below our final series: they get an average national income of 38.3 billions old francs for 1910-1913 (while we get 42.7 billions) and 26.6 billions for 1900-1909 (while we get 33.9 billions). The Villa

[^63]:    series are more sophisticated and more comparable to modern national accounts than the BLL series, so anchoring the entire BLL series to the Villa values for 1900-1909 and 1910-1913 appears to be the most reasonable option.
    ${ }^{7}$ Using the gross domestic product series provided by Toutain (1997, pp.54-57), again anchored to the Villa values for 1900-1909 and 1910-1913, we get an average value of 10.2 billions in 1820-1829 (vs 11.3 billions using the BLL series) and 26.2 billions in 1870-1879 (vs 28.6 billions using the BLL series); by construction, both series yield 42.7 billions in 1910-1913. The maximum gap between the Toutain and BLL series (which are based upon very different raw statistical material and methodologies) is less than $10 \%$, which is very small over a one-century-long period, and negligible for our purposes.
    ${ }^{8}$ We downloaded the complete set of recently released Insee retrospective 1979-2009 national wealth accounts series (i.e. balance sheets) on www.insee.fr on 15/09/2009. We used Insee tables 5.407 to 5.415 . As far as financial assets and liabilities are concerned, these tables are identical to those released by Banque de France (who is the primary producer of French financial accounts), except that the latter include more types of financial assets; on the other hand the advantage of Insee tables is that they also include tangible assets. It is preferable to use these Insee-Banque de France tables rather than the financial accounts released by international data collectors such as Oecd, Eurostat or the Imf, again because the former are more detailed and cover longer time spans. Insee-Banque de France balance sheets are estimated at market prices prevailing on December $31^{\text {st }}$ of each year; so our January $1^{\text {st }} 2009$ estimates are in fact December $31^{\text {st }} 2008$ estimates, etc., and our January $1^{\text {st }} 1979$ estimates are in fact December $31^{\text {st }}$ 1978 estimates. The estimates for 2008-2009 are likely to be slightly revised by Insee in the near future. For 2010 we assumed that asset prices between January $1^{\text {st }} 2009$ and January $1^{\text {st }} 2010$ declined as much as between January $1^{\text {st }} 2008$ and January $1^{\text {st }} 2009$ (i.e. $-5.4 \%$ on average); see section A5 below. Currently available Insee-Banque de France retrospective wealth accounts series cover only the 1979-2009 period, so for the 1970-1978 subperiod we had to use series that were previously published by Insee using less sophisticated concepts and methodology (see " 25 ans de comptes de patrimoines (1969-1993)", INSEE Résultats n³48 (Economie générale $\mathrm{n}^{\circ} 98$ ), december 1994); in order to ensure continuity, these 1970-1978 series were anchored to the 1979 values; more details are given in section A4 below.

[^64]:    ${ }^{9}$ The exact references are given in section A5 below.

[^65]:    ${ }^{10}$ Col. (14) of Tables A1 and A2 is borrowed from col.(1) of Table A10. See section A3 below.

[^66]:    ${ }^{11}$ For 1949-2008 we used Insee tables 3.101 to 3.601 and the "tableaux économiques d'ensemble" (downloaded from www.insee.fr on 15/09/2009). For 1896-1948 we used Villa's long.xls data base (downloaded from www.cepii.fr on 15/10/1998; these series are identical to those published in Villa (1994, pp.84-153), and have not been updated since then). All raw Insee and Villa series expressed in billions current currency are provided in the excel file AppendixTables(NationalAccountsData).xls (see Table A0). The file also includes the formulas used to construct all other tables.
    ${ }^{12}$ Net foreign capital income is equal to gross capital income inflow (capital income received by French residents on their foreign financial assets) minus gross capital income outflow (capital income received by foreign residents on their French financial assets), while net foreign labor income is equal to gross labor income inflow (labor income received by French residents while working abroad) minus labor income outflow (labor income received by foreign residents while working in France). In pre 1949 series we only observe net foreign capital income (not the gross flows), and foreign labor income was not recorded at all (given post 1949 values we set it to $0 \%$ for national income computations).
    ${ }^{13}$ I.e. gross inflow of taxes and unilateral transfers flowing from the rest of the world to French residents, minus gross outflow of taxes and unilateral transfers flowing from French residents to the rest of the world.
    ${ }^{14}$ In contrast, according to the Villa series, $\mathrm{FT}_{\mathrm{t}}$ was positive and fairly large ( $2 \%$ to $6 \%$ of national income) during the 1920s, which (partly) reflects German transfer payments. Note that we included all tax flows in $\mathrm{FT}_{\mathrm{t}}$ , including production taxes (D2 in ESA 1995 classification). According to ESA 1995 definitions, net foreign production taxes should actually be included in the primary income account (together with net foreign factor income $\mathrm{FY}_{\mathrm{t}}$ ), rather in the secondary income account (which should only include net foreign direct taxes, in addition to net foreign transfers); i.e. they should be included in the computation of national income $Y_{t}$ (and not only in the computation of national disposable income). However pre 1949 series are not sufficiently detailed to properly isolate net foreign production taxes (in the current sense) within $\mathrm{FT}_{\mathrm{t}}$; so it made more sense to adopt a simplified definition of national income and to omit this (small) term throughout the 18962008 period; in addition, the conceptual difference between foreign flows of production taxes vs other taxes is somewhat obscure.

[^67]:    ${ }^{15}$ Currently available Insee retrospective capital depreciation series cover only the 1978-2008 period (except for the government sector, where they start in 1949). For the 1896-1977 period we used the capital depreciation series provided by Villa (1994). Detailed depreciation series (broken down at the institutional production sector level) are given in the excel file.
    ${ }^{16}$ Following standard national accounts practice, $\mathrm{Y}_{\mathrm{ht}}$ is defined as the net-of-depreciation rental value of the housing fixed assets owned by households (including imputed rent). Note that this is (slightly) smaller than the total value of housing services produced in the economy, because a (small) fraction of the housing capital stock is owned by corporations and by the government.
    ${ }^{17}$ We define $\mathrm{Y}_{\text {set }}$ as the net product of the household sector minus $\mathrm{Y}_{\mathrm{ht}}$. Note that $\mathrm{Y}_{\text {set }}$ is (slightly) bigger than the net product of unincorporated businesses, since it also includes the (wage) labor income of domestic wage earners (i.e. wage earners directly employed by households in order to produce domestic services). It also includes the (wage) labor income of wage-earners employed by unincorporated businesses. This explains why the share of $\mathrm{Y}_{\text {set }}$ in national income is typically bigger than the share of self-employed in total employment (more on this below). The national accounts tables reported in Piketty (2001, pp.693-720) display lower estimates of $\mathrm{Y}_{\text {set }}$ than those reported in the more consistent series presented here. This is because Piketty (2001) used pre-1970 national accounts series based upon older concepts and definitions: the wage bill paid by unincorporated businesses (which was non negligible during the first half of the $20^{\text {th }}$ century, both in the rural and urban economy) was in effect attributed to the corporate sector in these older series, thereby resulting in an upward bias in the estimate of the corporate labor share (see below).
    ${ }^{18}$ In the same way as for wealth accounts (see below), and in order to simplify notations and tables, we include in the corporate sector both non-financial corporations and financial corporations. Separate series for non-financial and financial corporations are provided in the excel file.

[^68]:    ${ }^{19}$ In the same way as for wealth accounts (see below), all government levels are included (central and local government, social security administrations, as well as the non-profit sector). It is somewhat arbitrary to include the non-profit sector into the government sector (it could as well be included in the personal or corporate sectors). However this simplifies notations and tables. In any case the non-profit sector has always been relatively small in France (about 1\% of national income).
    ${ }^{20}$ This includes all "production taxes" in the national accounts sense (D2 in ESA 1995 classification), i.e. the sum of "product taxes" strictly speaking (D21 in ESA 1995 classification: this includes value-added taxes, excise duties, import taxes and various consumption taxes) and "other production taxes" (D29 in ESA 1995 classification: this includes a number of property taxes and non-social-contributions payroll taxes, see below), net of subsidies (D3 in ESA 1995 classification).
    ${ }^{21}$ This can be compared to the general VAT rate, which is currently $19.6 \%$ in France (the reduced rate is $5.5 \%$ ). However one must keep in mind that VAT revenues strictly speaking make only about half of total production taxes revenues (in 2008,136.8 billions $€$ out of 256.5 billions $€$ ). Note also that "factor price national income" is merely an accounting concept, and certainly does not imply that production taxes are entirely shifted to prices: first, some of the VAT itself is probably shifted to factor income, depending on sectoral supply and demand elasticities; next, some of the other taxes included in D2 ESA 1995 classification (e.g. a number of business and personal property taxes - "taxe professionelle", "taxe foncière", etc. - and non-social-contributions payroll taxes - "taxe sur les salaries", "versement transport", etc.) are closer to factor income taxes.
    ${ }^{22}$ See Figure A7.
    ${ }^{23}$ Available indexes of housing rent for France and Paris, divided by CPI, follow almost exactly the same pattern over the $20^{\text {th }}$ century. See e.g. Piketty (2001, pp.89-91, graphs 1-9 and 1-10).
    ${ }_{24}$ The residual profit share of the government sector was included in production taxes (see below).

[^69]:    ${ }^{25}$ I.e. over the past century public employment share rose from $2 \%-3 \%$ to about $20 \%$ of total employment, while self-employment share declined from about $50 \%$ to less than $10 \%$ of self-employment (see Piketty (2001, p.51, graph 1-4)). The self-employment sector output share $Y_{\text {seel }}\left(Y_{\mathrm{gt}}+Y_{\text {set }}+Y_{\mathrm{ct}}\right)$ was actually even larger than $50 \%$ around 1900 (it was as high as $65 \%-70 \%$ ), which can be accounted for by the fact that $\mathrm{Y}_{\text {set }}$ also includes the wages of wage-earners directly employed by households and unincorporated businesses (see above). Also the boundaries between unincorporated and corporate businesses in early $20^{\text {th }}$ century national accounts series are somewhat fragile (e.g. at that time many not-so-small manufacturing businesses were still unincorporated), so one would need to collect additional data in order to push further this kind of analysis.

[^70]:    ${ }^{26}$ Note that because we put aside all production taxes $T_{p t}$, our corporate capital and labor shares series always sum up to $100 \%$, which makes evolutions easier to interpret. The price to pay for this simplification is that we are implicitly assuming that that the component of production taxes $T_{p t}$ that is not shifted to prices is shifted proportionally to labor and capital factor income, which seems acceptable as a first approximation, but which strictly speaking might not be true.
    ${ }^{27}$ Due to sluggish output growth and rapid wage growth after the 1973-1974 oil shock.
    ${ }^{28}$ Due to wage freeze policies implemented after 1982-1983 by the newly elected socialist government.
    ${ }^{29}$ Here we naturally look at the net outflow of divided and interest paid by the corporate sector. During the 1990s-2000s, gross outflows and inflows have increased enormously in absolute terms, reflecting a large rise in financial linkages within the corporate sector.

[^71]:    ${ }^{30}$ Note the relatively large "other corporate transfers" term (about 3\%-4\% of net corporate product, i.e. 1\%$2 \%$ of national income, throughout the 1949-2008 period), which we define as the net value of various transfers paid by the corporate sector (D61+D62+D71+D72+D75 in ESA 1995 classification): D61-62 relate to employer provided social contributions and benefits transfers and sum to (close to) zero; D71-72 relate to insurance premiums and claims transfers and sum to (close to) zero; D75 is the only significant term; it relates to "miscellaneous current transfers" and typically includes unilateral transfers to the non-profit and personal sectors. This ought to be further investigated, especially given that such transfers are not properly recorded in pre-1949 series.
    ${ }^{31}$ See Figures A4 and A5. One should use the series reported here rather than the gross profit share series reported in Piketty (2001, pp.703-705; 2003, p.1022, fig. 4). Both sets of series are broadly similar, but our older functional shares series were less complete and suffered from various deficiencies. In particular, pre1949 corporate capital shares were underestimated, due to the fact that the wage bill paid by households and unincorporated businesses was (wrongly) attributed to the corporate sector (see above).
    ${ }^{32}$ It is possible that this sharp rise is over-estimated somewhat. However all raw statistical series suggest that corporate output was indeed growing faster than corporate wages during the 1896-1913 period. We return below on $19^{\text {th }}$ century functional share estimates (see Table A12).
    ${ }^{33}$ See Malissen (1953), who on the basis of interwar corporate income tax tabulations argues that the exploratory, semi-official national accounts constructed for year 1938 by Insee overestimate retained earnings. Since Villa anchors some of his series on these 1938 semi-official accounts, this criticism also applies to his series as well. See Piketty (2001, p.716).

[^72]:    ${ }^{34}$ The fact that $\alpha_{\mathrm{ht}}=100 \%$ is simply the consequence of the standard national-accounts definition of housing services: the value of housing services is defined is the pure rental value of housing, i.e. excluding all labor inputs that can increase the value of housing services (i.e. cleaning services, etc.).
    ${ }^{35}$ The other standard way of breaking down self-employed income into capital and labor income components is to attribute to self-employed workers the same average labor income compensation as the wage earners of the corporate sector. We found that this alternative computation delivers very similar results regarding the pattern of the aggregate capital share $\alpha_{t}$. A third and somewhat more satisfactory way to break down selfemployment income would be to attribute to self-employment capital stock the same rate of return as for the rest of the economy. This is more data demanding, however.
    ${ }^{36}$ The fact that $\alpha_{\mathrm{gt}}=0 \%$ simply follows from the standard national-accounts definition of government net product: in national accounts, the gross value of non-market output is estimated on a cost basis, i.e. summing up labor cost, intermediate consumption and estimated capital depreciation; so that the net valueadded is simply equal to labor cost. Note that the government sector also produces small (but positive) market output and receives residual payments from personal and corporate sectors for these goods and services, so that strictly speaking the net profit share of the government sector is not exactly equal to zero in national accounts. But it very small (always less than $0.5 \%$ of net government product in French accounts), so in order to simplify exposition and tables, we choose to conventionally set $\alpha_{\mathrm{gt}}=0 \%$ and to attribute this small profit term to production taxes (see excel file for detailed series and formulas).
    ${ }^{37}$ Of course this is purely conventional: the government sector does use capital input (administrative buildings, schools, hospitals, etc.), and one could very well decide to attribute a positive return to these assets, which would raise national income $Y_{t}$. E.g. the estimated value of government tangible assets was around $75 \%$ of national income during the 2000 s (see Table A13 below); if one attributes a $4 \%$ average return to these assets, this would raise national income by $3 \%$. This not really relevant for our purposes, since this extra capital income is not distributed to any private individual (it is simply enjoyed by everyone), so this does not affect average returns to private wealth (in case the government sector uses capital inputs owned by other sectors, then the corresponding capital income flow is recorded).

[^73]:    ${ }^{38}$ Except during the interwar period, following the large rise in public debt during World War 1. Also note that net government interest payments were negative during the late 1960s and early 1970s, i.e. interest and dividend on government financial assets slightly exceeded interest payments. It is maybe surprising that net capital income received by government was not more strongly positive during the period running from World War 2 to the 1980s, given the large government equity participations in corporations at that time. This could reflect the fact that the government was getting relatively low returns on its assets, and/or was keeping a large share of the profits as retained earnings to finance new investment in publicly owned companies (we know that aggregate retained earnings were very large during the 1950s-1960s, but we do not know the break down by ownership status; it seems likely that retained earnings were particularly large in publicly owned companies), and/or was implicitly using some of the returns to pay better wages in publicly owned companies. During the 2000s, the estimated value of government financial liabilities (public debt) was about $80 \%$ of national income, and that of government financial assets (e.g. shares in public utility companies) was about 50\% of national income (see Table A13 below).

[^74]:    ${ }^{39}$ See Figures A7 and A8.

[^75]:    ${ }^{40}$ As explained above, we include in this category all "production taxes" (D2 in ESA 1995 classification), i.e. the sum of "product taxes" strictly speaking (D21) and "other production taxes" (D29), net of subsidies (D3).
    ${ }^{41}$ We include in this category all "current taxes on income and wealth" (D5 = D51+D59 in ESA 1995 classification) paid by the corporate sector (in practice D59=0 for corporations).
    ${ }^{42}$ We include in this category all "current taxes on income and wealth" (D5 = D51+D59 in ESA 1995 classification) paid by the personal (household) sector, as well as bequest and gift taxes, which are treated separately in national accounts (D91D in ESA 1995 classification).
    ${ }^{43}$ We include in this category all "social contributions" (actual and imputed) (D61 in ESA 1995 classification) received by the government sector.
    ${ }^{44}$ More precisely, we assume that $T_{\text {Lit }}=\left(T_{i t}-T_{B t}\right) x\left(Y_{L t} S_{C}+Y_{R t}\right) /\left(Y_{L t}-S_{t}+Y_{R t}+0.5 x Y_{K_{t}}{ }^{*}\right)$ and $T_{K i t}=\left(T_{i t}-T_{B t}\right) x$ $\left(0.5 x \mathrm{~K}_{\mathrm{Kt}}{ }^{*}\right) /\left(\mathrm{Y}_{\mathrm{Lt}}-\mathrm{SC}_{\mathrm{t}}+\mathrm{Y}_{\mathrm{Rt}}+0.5 \mathrm{x} \mathrm{K}_{\mathrm{Kt}}{ }^{*}\right)$, where $\mathrm{Y}_{\mathrm{Rt}}$ is replacement income defined below (social contributions are deductible for income tax purposes, but replacement income is taxable). Detailed computations are provided in the excel file.
    ${ }^{45}$ Assuming a constant (taxable $\left.\mathrm{Y}_{\mathrm{Kt}}{ }^{*}\right) / \mathrm{Y}_{\mathrm{Kt}}{ }^{*}$ factor equal to $50 \%$ throughout the $1896-2008$ period is of course very rough and ought to be improved. The true factor was somewhat larger than $50 \%$ in the early $20^{\text {th }}$ century (e.g. imputed rent was subject to the income tax at that time), and is somewhat below $50 \%$ in the late $20^{\text {th }}$ century and early $21^{\text {st }}$ century (special exemptions for capital income have become more and more numerous in recent decades). However we tried a number of alternative, less rough assumptions (such as using the observed capital income tax base), and we found that the impact on overall tax rates series was relatively limited, so we chose this simpler assumption. The complication comes from the fact that one would

[^76]:    also need to take into account tax progressivity (capital incomes are typically higher up in the distribution than labor incomes); so a complete computation would require estimating the full joint distributions of capital income (including tax exempt capital income) and labor income. This falls far beyond the scope of the present research.

[^77]:    ${ }^{46}$ Replacement income $Y_{R t}$ is defined as the sum of "social security benefits in cash" (D621 in ESA 1995 classification) and "unfunded employee social benefits" (D623) paid by the governement; pure transfers TR $_{0}$ are defined as "social assistance benefits in cash" (D624) paid by the government; total government monetary transfers $\mathrm{TR}_{\mathrm{t}}$ are defined as the sum of the two. D624 transfers include all means-tested cash transfers, while D621-D623 include earnings-related transfers (mostly pensions and unemployment benefits). We also report on col. (19) of Table A9 the value of in-kind government transfers, i.e. "social transfers in kind" (D63), defined as the sum of "social benefits in kind" (D631: health insurance reimbursement and benefits, housing benefits, etc.) and "transfers of individual non-market goods and services" (D632: value of free education services provided by the government, etc.).
    ${ }^{47}$ The slight superiority of capital tax rate over (net-of-replacement-taxes) labor tax rate comes from the fact that the corporate income tax is a flat tax with high tax rate (typically $30 \%-50 \%$ since the 1950s), while the personal income tax is progressive, with a lower average tax rate. However the many capital tax exemptions (imputed rent, etc.) tend to counterbalance this effect, and it is possible that the true capital tax rate is actually (slightly) below the labor tax rate.
    ${ }^{48}$ Alternatively, if one defines $T_{\mathrm{ft}}=T_{\mathrm{pt}} / Y_{\mathrm{t}}=\mathrm{T}_{\mathrm{pl}} /\left(1+\mathrm{T}_{\mathrm{pt}}\right)$ the implicit factor income tax rate associated to production taxes, one gets the equivalent formulas $\mathrm{T}_{\mathrm{kt}}=1-\left(1-\mathrm{T}_{\mathrm{kt}}\right)\left(1-\mathrm{T}_{\mathrm{tt}}\right)$ and $\mathrm{T}_{\mathrm{Lt}}=1-\left(1-\mathrm{T}_{\mathrm{Lt}}\right)\left(1-\mathrm{T}_{\mathrm{tt}}\right)$.

[^78]:    ${ }^{49}$ We note $\mathrm{T}_{\mathrm{Lt}}{ }^{*}$ this corrected labor tax rate (i.e. after deduction of "replacement taxes").
    ${ }^{50}$ See above (footnotes 21-22).
    ${ }^{51}$ Think of the price of cars under a VAT with full deductibility of capital goods (i.e. immediate expensing, such as the French VAT system): the price is lower when you buy cars for investment purposes than when you buy cars for consumption purposes.

[^79]:    ${ }^{52}$ The only noticeable impact would be on our estimates of the share of inheritance resources in total disposable resources by cohort (see Appendix D4). If productions taxes fall entirely on factor incomes, as we assume, then inheritance resources pay no production taxes. However if part of production taxes are pure consumption taxes, then they also fall on successors when they use they inheritance resources to purchase consumption goods. So our estimates of $\alpha^{\star *}$ and $\gamma^{\star}$ should be reduced somewhat in order to take this into account.
    ${ }^{53}$ Because replacement income $Y_{R t}$ represents the vast majority of government monetary transfers $T R_{t}$, and in order to simply tables and notations, we omit pure transfers $\mathrm{TR}_{\mathrm{ot}}$ from our definition of disposable income (see Table A9, col. (19)). We also omit "other corporate transfers" (see below).
    ${ }_{54}$ If one were to add the value of all services produced by the government (police, national defence, justice, etc.), then by definition disposable income would be as large as national income.

[^80]:    ${ }^{55}$ After-tax capital income $Y_{\text {Kdt }}$ is defined as capital income $Y_{K t}{ }^{*}$ (col. (1), Table A8), minus capital taxes $T_{K t}$ (col. (6), Table A9), minus "other corporate transfers" (col. (14), Table A7). This latter term raises difficult interpretation issues, and it is unclear whom it should be attributed to (see above). In effect, we choose to treat "other corporate transfers" as a tax: we include this term in the definition primary capital income (this is common practice in the analysis of profit shares), and we exclude it from the definition of disposable income (this is common practice in the analysis of household capital income). We note $\mathrm{T}_{\mathrm{Kt}}{ }^{*}$ this corrected capital tax rate, i.e. after inclusion of "other corporate transfers" (by construction, $\mathrm{Tkt}^{*}=1-\alpha_{\mathrm{dt}} / \alpha_{\mathrm{t}}{ }^{*}$, where $\alpha_{\mathrm{dt}}=Y_{\mathrm{kdt}} \mathcal{Y}_{\mathrm{t}}$ is the after-tax capital income share in national income). In the 2000s, the corrected capital tax rate $\mathrm{T}_{\mathrm{kt}}{ }^{*}$ appears to be over $40 \%$, while the uncorrected capital tax rate $\mathrm{T}_{\mathrm{Kt}}$ is about $35 \%$ (see Table A11, col. (8) \& (11)).
    ${ }^{56}$ After-tax labor income $Y_{\text {Ldt }}$ is defined as labor income $Y_{\text {Lt }}$ (col. (8), Table A8), minus social contributions $\mathrm{SC}_{t}$ (col. (5), Table A9), minus $\mathrm{T}_{\mathrm{Lit}} \times\left(\mathrm{Y}_{\mathrm{Lt}}-\mathrm{SC}_{t}\right) /\left(\mathrm{Y}_{\mathrm{Lt}} \mathrm{SC}_{t}+\mathrm{Y}_{\mathrm{Rt}}\right)$, where $\mathrm{T}_{\mathrm{Lit}}$ is the estimated labor share of personal taxes (see above). Personal taxes rely on net-of-social-contributions labor income and on replacement income, and we assume that the average tax rate is the same on the two.
    ${ }^{57}$ After-tax replacement income $Y_{\text {Rdt }}$ is defined as replacement income $Y_{\text {Rt }}$ (col. (17), Table A9), minus $T_{\text {Lit }} X$ $\mathrm{Y}_{\mathrm{Rt}} /\left(\mathrm{Y}_{\mathrm{Lt}}-\mathrm{SC}_{\mathrm{t}}+\mathrm{Y}_{\mathrm{Rt}}\right)$ (see above).
    ${ }^{58}$ See Figure A9 vs. Figure A7.
    ${ }^{59}$ Although this seems like the most logical way to proceed as a first approximation, our way of dealing with retained earnings is far from being fully satisfactory. In particular, one would need to take away the fraction of retained earnings which corresponds to government participations in the corporate sector (it is possible that this was a significant fraction in the 1950s-1960s), which unfortunately historical national accounts series do not allow to do. In principle one should also deduct the fraction which corresponds to foreign participations (and add the retained earnings of foreign companies which corresponds to the participations of French residents). Given that the net foreign asset position of France is close to zero, the net effect must be relatively small.

[^81]:    ${ }^{60}$ See Figure A10. Note that because we probably overestimate the effective tax burden falling on capital in the recent period (see above), we probably under-estimate somewhat the level of the after-tax capital share in the 2000s. In particular the apparent decline of the after-tax capital share in the late 1990s and early 2000s (and corresponding rise in the after-tax labor share) is likely to be exaggerated (it is parly due to the CSG tax reform - i.e. gradual transfer of some social contributions levied on labor income to a broad based proportional income tax - and the fraction of capital income subject to CSG is in fact smaller than our presumed constant-over-time $50 \%$ ratio). Note also the large rise of the capital income share in household income (from about $10 \%$ in the 1950s to about $20 \%$ in the 1990s) reported in our older series (Piketty (2001, pp.710-711; 2003, fig.4, p.1022) stems from the fact that we omitted in these older series to include retained earnings, and most importantly to include self-employment capital income. In our new corrected series we assumed for simplicity that the capital and labor shares were the same in the self-employment sector than in the corporate sector (which by construction implies than changes in the relative importance of the two sectors has no impact on aggregate capital share); this is imperfect, but better as a first approximation than the zero capital share assumption implicit in our older series.
    ${ }^{61}$ See Figure A11. As was noted above, it is possible that the retained earnings levels reported for the interwar period are over-estimated somewhat.

[^82]:    ${ }^{62}$ Col. (9) of Table A10 is defined as col. (8) of Table A9 (private savings) plus col. (15) of Table A18 (estimated war destructions as a fraction of national income).
    ${ }^{63}$ In particular the $19^{\text {th }}$ century national accounts constructed by Bourguignon and Levy-Leboyer (1985) and Toutain (1997) are pure production-based accounts: they offer decompositions by industrial production sectors, but not by income categories.
    ${ }^{64}$ The capital share $\alpha_{\mathrm{t}}$ was then computed as one minus the labor share. The capital share $\alpha_{\mathrm{t}}{ }^{*}=\alpha_{\mathrm{t}}+\alpha_{\mathrm{gt}}$ (col. (5) of Table A12) was computed by assuming for simplicity that net government interest $\alpha_{\mathrm{gt}}$ was equal to $2.0 \%$ of (factor-price) national income throughout the 1820-1900 period, i.e. the same approximate value as in 1900-1913. Government accounts show that $\alpha_{\mathrm{gt}}$ was indeed relatively stable around $2 \%$ over the $1820-$ 1913 period, except during the 1870-1900 period, when it reached $3 \%-3.5 \%$, following the 1870-1871 war and the ensuing rise in public debt (see e.g. Toutain (1997, p.86); see also Fontvieille (1976)). This is ${ }_{65}$ negligible for our purposes.
    ${ }^{65}$ Detailed computations and formulas are reported on col.(3)-(4) of Table A12 and col.(13)-(14) of Table A18. We used the SGF-March manufacturing-sector nominal wage index (as reported by Toutain (1997, p.165)), and we multiplied it by total adult population in order to compute a nominal wage bill index. Of course wage earners made a smaller fraction of the labor force in the early $19^{\text {th }}$ century than in the late $19^{\text {th }}$ century. But because we attempt to compute the labor and capital shares in total national income, and since we do not have $19^{\text {th }}$ century series on the relative shares of the corporate vs self-employment sectors in national income, this is the right thing to do, at least as a first approximation. In effect we are assuming that the SGF-March nominal wage index provides an acceptable approximation of how average individual labor

[^83]:    compensation per adult (wage labor and self employment labor, urban and rural) has evolved in France over the 1820-1900 period. Note also that rental income plays no role in our simple computations: in effect we are implicitly assuming that the share of rental income in national income has remained approximately constant over the 1820-1913 period; available estimates indeed suggest that housing rents have been relatively stable around $5 \%-8 \%$ of national income in the $19^{\text {th }}$ century, possibly with a rise during the second half of the century; see the estimates of net housing rents given by Toutain (1997, p.113)).
    ${ }^{66}$ Our nominal wage index series seem to deliver lower-bound estimates of the rise of the capital share between 1820-1830 and 1850-1860. According to alternative wage series (such as those reported by Bourguignon and Levy-Leboyer (1985, pp.333-337)), there was virtually no wage growth at all until the 1850 s; using such series, one would find capital shares over $50 \%$ at mid $19^{\text {th }}$ century. Of course these wage series (including the SGF-March index we are using) are fragile and are generally restricted to industrial lowskill or medium-skill workers (i.e. a relatively small fraction of the workforce of the time). However one would need to assume enormous wage growth for other segments of the workforce in order to compensate manufacturing wage stagnation and undo the capital share pattern.
    ${ }^{67}$ The capital share pattern that we find for 1890-1899, 1900-1909 and 1910-1913 using our wage index method is consistent with the Villa 1896-1913 series. Villa's series might exaggerate somewhat the rise of the capital share for this time period. But qualitatively such a pattern seems more consistent than the 19001913 functional shares stability postulated by Colson (1918, livre 2, p.403): Colson constructs estimates for the structure of private incomes for years 1900 and 1913, using concepts and methods similar to those used by Dugé de Bernonville in his interwar series; however Colson provides limited information on his data sources, which appear to be much less sophisticated than the detailed output and wage indexes used by Villa; in addition there are reasons to believe that Colson (like a number of economists of the time) was strongly attached to the functional stability conclusion per se. Finally, note that the findings of Bouvier, Furet and Gillet (1965), who collected and analyzed book accounts of large companies in France during the $19^{\text {th }}$ century, are consistent with the rise of the capital share in 1896-1913, as well as with our pattern for earlier periods: they find high profit growth during the 1850-1873 period, low profit growth during the 1873-1896 period, and again booming profits in 1896-1913; unfortunately their data is too incomplete to compute profit and labor shares (too small sample, and imperfect distinction between wage bill and intermediate consumption in book accounts), and they have even fewer companies with proper accounts prior to 1850 .

[^84]:    ${ }^{68}$ One would need to collect new raw data on wages in larger segments of the urban and rural economy of the time in order to settle the issue. Note however that the possibility that capital shares attained levels as large as $45 \%$ (or even larger) in $19^{\text {th }}$ century economies is certainly plausible. In today's less developed countries one often finds capital shares closer to $40 \%-50 \%$ (or even larger) than to the standard $20 \%-30 \%$ figures found in today's developed countries. Possible explanations for this range from technological stories (e.g. human capital might play a structurally less important role in ancient production functions than in modern ones) to institutional stories (e.g. unions and strikes were virtually banned in a country like France prior to the 1850 s - 1860 s; it is possible that labor bargaining power was particularly low in France during the first half of the $19^{\text {th }}$ century, and more generally in less developed economies). To our knowledge this is very much an open issue.
    ${ }^{69}$ The government accounts of the time indeed suggest that aggregate tax revenues during the $19^{\text {th }}$ century were approximately stable around $8 \%-9 \%$ of national income (see e.g. Toutain (1997, p.86); see also Fontvieille (1976)). Small time variations around this approximately constant level are negligible for our purposes.
    70 For 1900-1909 and 1910-1913 we found that the average capital tax rate was slightly larger than the average labor tax rate, due to relatively large bequest and gift tax revenues. The bequest and gift tax however raised somewhat lower revenues before the 1901 estate tax reform. Note also the tax on interest and dividend income that was in force in 1900-1913 did not exist during most of the $19^{\text {th }}$ century (the "impôt sur le revenu des valeurs mobilières" - IRVM - was introduced in 1872; this rudimentary income tax system was extended to other income sources in 1914-1917). In any case, the tax rates of the time were all pretty small by modern standards, and that these small variations can be neglected as a first approximation.
    ${ }^{71}$ I.e. we assumed that government transfers (replacement income) were permanently equal to $1.0 \%$ of national income throughout the 1820-1899 period, i.e. approximately the same level as in 1900-1913 (see references above). It follows from our assumptions on government interest ( $2.0 \%$ ), taxes ( $8.0 \%$ ) and transfers (1.0\%) that personal disposable income was equal to $95.0 \%$ of national income throughout the 1820-1899 period ( $\mathrm{Y}_{\mathrm{dt}}=\mathrm{Y}_{\mathrm{t}}-\mathrm{T}_{\mathrm{t}}+\mathrm{Y}_{\mathrm{Rt}}+\mathrm{Y}_{\mathrm{Kgt}}$ ).
    ${ }^{72}$ In order to compute total private savings, we summed up the net domestic investment and net foreign investment series constructed by Bourguignon and Levy-Leboyer (1985, pp.323-327 \& 339-342). Note that according to these estimates, from the 1850s up until 1913, net foreign investment made a substantial part of total private savings (at least $20 \%-30 \%$, and up to $40 \%$ during the 1860 s and 1890 s-1900s). This is qualitatively and quantitatively consistent with the rising share of foreign assets in total private wealth during

[^85]:    this period (see section A4 below). These BLL investment series should be preferred to the investment series provided by Toutain (1997, pp.77-78), which do not include foreign investment; in addition, Toutain's domestic investment series look definitely too low (with net domestic investment rates below $5 \%$ of national income during most of the $19^{\text {th }}$ century), and inconsistent with the observed pattern of private wealth-national income ratios.
    ${ }^{73}$ We might however overestimate the tax burden falling on capital during the recent period.

[^86]:    ${ }^{74}$ Capital gains sometime pay (moderate) taxes. However capital gains tax revenues are already taken into account in corporate and personal income taxes (in effect we attribute them to the capital income flow), so they do not need to be added here.
    ${ }^{75}$ In particular, the book accounts of large $19^{\text {th }}$ century French companies collected by Bouvier et al (1865) display high profit rates in the 1850s-1860s, declining profit rates in the 1870-1900 period, and rising profit rates from the late 1890s until 1913 (see above). According to net rental income estimates of Toutain (1997, p.113), the rate of return on housing assets was relatively stable around $4 \%$ during the 1800-1913 period. l.e. most of the $19^{\text {th }}$ century movements in the overall rate of return on private wealth seems to come from

[^87]:    non-housing productive assets (particularly in the booming manufacturing sector). Note also that Banque de France (and Bank of England) interest rates were on average larger between the 1820s and 1860s (typically $4 \%$, and sometime as much as $5 \%$ ) than during the 1870-1900 period (when they declined to about 3\%); see e.g. the series reported by Bourguignon and Lévy-Leboyer (pp.338-342). Such interest rate series raise serious interpretation issues, however: they could also reflect changes in central bank and government finances credibility, at least in part; in any case, given than public debt represents such a small part of aggregate private wealth (usually less than 10\%), it seems unlikely that movements in this particular return (wherever they come from) have driven movements in the overall rate of return on private wealth.
    ${ }^{76}$ See section A1 above for exact references to the Insee-Banque de France tables. We did not make any correction to the Insee-Banque de France raw balance sheets.
    ${ }_{78}^{77}$ Raw values expressed in current billions euros are provided in the excel file.
    ${ }^{78}$ We use the words "tangible assets" for the sake of concreteness, but we actually include in this category all non-financial assets, as defined by international balance sheets official guidelines ("AN" in ESA 1995 classification code; this also includes a number of intangible assets such as computer software and patents, as well as inventories and valuables; see ESA 1995 manual).

[^88]:    ${ }^{79}$ See Table A15 below for the decomposition between housing and non-housing tangible assets.
    ${ }^{80}$ In the same way as for income accounts (see above), we include in the government sectors all government levels, as well as the (tiny) non profit sector. Detailed series are available in the excel file.

[^89]:    ${ }^{81}$ From a conceptual perspective, this naturally raises the issue as to whether we should exclude the government sector net product from our national income denominator $Y_{t}$ (given that the corresponding tangibles assets used to produce government net product are excluded from the private wealth numerator $\mathrm{W}_{\mathrm{t}}$ ). I.e. with our definitions a country with a rising proportion of tangible assets owned by the government (and a rising proportion of the population employed by the government) will go through a mechanical decline in $W_{t} / Y_{t}$ and $B_{t} / Y_{t}$ ratios (this would simply reflect the fact that public schools, hospitals, museums etc. cannot be privately owned and transmitted through inheritance). The reason why we finally decided to stick to our definitions is because in practice the large and growing tangible assets owned by the government have been approximately compensated by the rise of public debt, so that the share of government net wealth in national wealth is almost as small today as what it was one century ago. In effect, it is almost as if private individuals owned public tangible assets via public debt.
    ${ }^{82}$ This seems to be due to the fact that during the 1990s-2000s a number of public utilities services were turned into private corporations with large and rising equity capitalization (and in which the government kept important financial participations). For instance, today's government financial portfolio includes large equity positions in France Telecom and EDF. To some extent these have compensated for the privatization of financial assets in the banking and manufacturing sectors (especially given that the latter were lowly valued in the 1970s-1980s, prior to their privatization).

[^90]:    ${ }^{83}$ In the same way as for income accounts (see above), and in order to simplify notations and tables, we include in the corporate sector both non-financial corporations and financial corporations. Separate series for non-financial and financial corporations are provided in the excel file. Note also that throughout this appendix we use unconsolidated balance sheets (i.e. financial assets and liabilities of the corporate sector include claims of French corporate entities on other French corporate entities). Consolidated balance sheets covering the 1978-2009 period were recently released by Banque de France, but are not reported here.
    ${ }^{84} \mathrm{~L}_{\mathrm{ct}}{ }^{e}$ is defined as the total value of "shares and other equities" financial liabilities of the corporate sector (AF5 in ESA 1995 classification codes), while $L_{c t}{ }^{d}$ is defined as the total value of debt-like financial liabilities, i.e. all non-equity financial liabilities (AF1+AF2+AF3+AF4+AF6+AF7 in ESA classification codes for financial assets and liabilities; see ESA 1995 manual). Note that in international balance sheets guidelines (ESA 1995), as well as in French private accounting practice, equity value is conventionally included in the financial liabilities of the corporate balance sheet.

[^91]:    ${ }^{85}$ This is particularly puzzling if one considers the fact that many non-financial assets (typically intangible assets such trade marks, firm reputation, etc.) are not properly taken into account in the balance sheets of corporations. In principle the stock market should take these assets into account, which should push measured Tobin's Q ratios structurally above $100 \%$. Note also that $Q$ ratios seem to be approximately the same for publicly traded and non publicly traded firms (following ESA 1995 guidelines, the value of private equity in Insee-Banque de France balance sheets is estimated using observed valuations for quoted shares and $Q$ ratios, controlling for industrial sector and company size, and including a discount for lower liquidity, based upon recent private equity transactions; this is of course imperfect, but we have no reason to believe that we can improve these estimates).
    ${ }^{86}$ Wright finds Tobin's Q ratios around $70 \%-80 \%$ for the US corporate sector in the 1990 s, i.e. approximately the same levels as those we find for France. Wright uses balance sheets released by corporations (i.e. book accounts relying upon private accounting concepts and methods) rather than national accounts balance sheets, but to a large extent his arguments also apply to the latter. Note that one also finds U.S. Q ratios around $70 \%-80 \%$ in the 2000s if one uses the balance sheets released by the Federal Reserve (see e.g. Flows of Funds Accounts of the United States, Sept. 18 2008, p.95, table B102, line 38). For such computations it is important to use Federal Reserve balance sheets (which include all tangible assets, including land values, using concepts and methods that are broadly similar to the Insee-Banque de France balance sheets) rather than NIPA fixed assets tables (which exclude land values).

[^92]:    ${ }^{87}$ Except if the national accounts statisticians overvaluation of corporate tangible assets also applies to personal tangible assets, in which case our private wealth estimates should actually be corrected downwards. It is likely however that the valuation problems for personal tangible assets (which currently consist mostly of real estate property) are less severe than for corporate assets. Also one additional reason explaining the overvaluation of corporate assets might be that private companies have an obvious incentive to make their book value look larger than their equity value (national accounts statisticians are in principle immune to corporate creative accounting, since they develop their own methods and concepts to estimate corporate balance sheets; but in practice they have little choice except relying - at least in part - on values reported in corporate book accounts). Clearly this problem does not apply to the personal sector (if anything, private individuals tend to under-report their assets in wealth surveys; but national accounts statisticians rely very little on wealth surveys anyway, at least in France).
    ${ }^{88}$ This kind of political threat argument can hardly explain why Tobin's Q ratios are lower than $100 \%$ in the 1990s-2000s. But it certainly contributes to explain the very low Q ratios observed in France in the late 1970s-early 1980s (when a socialist-communist alliance came to power with a large nationalization programme), and more generally the historically low levels of asset prices observed in the West during the Cold War period (and particularly in the immediate postwar period).

[^93]:    ${ }^{89}$ According to Atkinson (1972, pp.6-7), such a correction can lead to upgrade aggregate U.K. personal wealth by as much as $25 \%$. In the case of France, our best guess is that a substantial part of the upgrade (if any) should be attributed to the government sector rather than to the personal sector (it is likely that government equity participations in a number of public or quasi public unquoted corporate entities are undervalued). In any case, note that measurement errors of the order of $20 \%-25 \%$ of private wealth (at the very most) would not seriously affect our key results regarding long run patterns.
    ${ }^{90}$ Note that by definition the net foreign asset position is equal to total financial assets minus total financial liabilities of French resident sectors (personal, government and corporate sectors). I.e. $W_{F t}=F A_{t}-F L_{t}=A_{p t}+$ $A_{g t}+A_{c t}-L_{p t}-L_{g t}-L_{c t}$. E.g. on January $1^{\text {st }} 2009$ the negative foreign asset position equal to $-5 \%$ of national income is equal to $+135 \%$ (positive financial asset position of personal sector) - 50\% (negative financial asset position of government) - 90\% (negative financial asset position of corporate sector, including equity value in liabilities).

[^94]:    ${ }^{91}$ The share of self-employment in total employment was as large as $25 \%-30 \%$ in France during the 1960s, and it is now less than $10 \%$ (see Piketty (2001, p.51, graph 1-4)). Note however the share of non-housing personal tangible assets in private wealth (as we measure it) is almost certainly an overestimate of the true share of the productive assets of the self-employed in private wealth. First, non-housing personal tangible include many assets (e.g. valuables, non-agricultural land, etc.) that have little to do with self-employed productive assets. We computed the value of housing tangible assets $\mathrm{K}_{\mathrm{pt}}{ }^{\mathrm{h}}$ as the value of "residential dwellings" (AN1111 in ESA 1995 classification codes), plus an estimate of the corresponding land value (we allocated the value of "land underlying buildings and structures" AN2111 proportionally to AN1111 and to AN1112 "other buildings and structures"); non-housing tangible assets $K_{p t}{ }^{n}$ was then simply computed as a residual $K_{p t}-K_{p t}{ }^{h}$ (see excel file for raw data and formulas). So by construction $K_{p t}{ }^{n}$ includes all non-housing, non-self-employed assets. Also, we attributed total personal financial liabilities to housing assets, thereby assuming that household debt consists entirely of mortgage debt. This is an acceptable approximation for the 1990s-2000s, but in the 1970s it is likely that a larger fraction of personal debt should be attributed to the self-employed. As a consequence the series reported on Tables A15a-A15b probably underestimate the net value of housing assets and over-estimate the value of non-housing assets in the early 1970s. Finally, as was noted above, pre-1978 balance sheets are more rudimentary and less precise than post-1978 series.
    ${ }^{92}$ Equity assets are defined as "shares and other equities" (AF5 in ESA 1995 classification codes). Public equity and mutual funds are defined as the sum of "quoted shares" (AF511) and "mutual funds shares" (AF52); private equity is defined as the sum of "unquoted shares" (AF512) and "other equity" (AF513). Nonequity assets are defined as the sum of all other financial assets: "currency and deposits" (AF2), "securities other than shares" (AF3), "loans" (AF4), "insurance technical reserves" (AF6), and "other accounts" (AF7).

[^95]:    ${ }^{93}$ According to ESA 1995 classification, "insurance technical reserves" (AF6) can be broken down into the value of "life insurance reserves" (AF611) and the value of "pension funds reserves" (AF612). However in the French balance sheets compiled by Insee-Banque de France, "pension funds reserves" are equal to zero by construction, i.e. "insurance technical reserves" are entirely allocated to "life insurance reserves". We took the full value of "insurance technical reserves" (AF6) as our estimate of life insurance assets (col. (11) of Tables A15a-A15b), with no correction.
    ${ }^{94}$ Unfortunately, the data published by insurance companies (FFSA) appears to be insufficient to compute a precise estimate of the annuitized fraction of life-insurance assets. One could think of using published payment flows to beneficiaries at the death of policy-holders. These annual flows currently appear to be relatively small, typically less than $1 \%$ of total life insurance reserves (around $5-10$ billions euros, out of over 1200 billions euros in life insurance reserves; see Rapport annuel FFSA 2008, pp.31-33), i.e. slightly less than the aggregate mortality rate $m_{t}$, and substantially less than the aggregate inheritance-wealth ratio $B_{t} / W_{t}$ $=\mu_{t}^{*} \mathrm{~m}_{\mathrm{t}}$ (see Table A3 above). However it is unclear how exactly insurance companies compute these payment flows to non-policy-holders beneficiaries: they apparently include only the payments corresponding to the explicit death insurance clause stipulated in life insurance contracts (i.e. the lump sum payment to beneficiaries conditional upon the death of the policy-holder). Most life insurance contracts in France are merely temporary term savings contracts (typically 8 -year-long), with a small explicit death insurance dimension, so that most payment flows mechanically return to policy-holders themselves, and possibly to their heirs in case they die (but these payments to heirs then do not seem to be counted as "death insurance" payments). Also note that we do not know from available data which fraction of the payment flows going to policy holders is used to repurchase new life insurance contracts and which fraction is used to purchase other assets, which may end up being transmitted to heirs (life insurance assets in France carry tax advantages not only at the time of wealth transmission, but also during accumulation: for the most part flow returns are being re-capitalized net of income tax).
    ${ }^{95}$ According to wealth surveys and to estate tax returns.
    ${ }^{96}$ This is because consumer durables do not generate flow returns in income accounts, and therefore are not treated as investment goods.
    ${ }^{97}$ Note that in their computation of bequeathable aggregate wealth using Federal Reserve balance sheets, Kopczuk and Saez (2004, NBER WP version, pp.44-47) keep the full value of life insurance reserves (as we do here), i.e. they assume that $100 \%$ of the value of life insurance reserves is bequeathable; but they keep only the cash surrender value (CSV) of pension funds reserves (i.e. the value of pensions that remains upon death), ranging from $5 \%$ of pension funds reserves for traditional defined benefits pension schemes to $100 \%$ for recent defined contributions pension schemes. Social security pensions cannot be transmitted to heirs and are naturally excluded from bequeathable wealth, both by Kopczuk-Saez and in the present research.

[^96]:    ${ }^{98}$ See Appendix B1.

[^97]:    ${ }^{99}$ It would indeed make no sense at all to use estate-multiplier-based national wealth estimates in order to compute the inheritance flow. Nineteenth century economists were so confident in the W/B=H estate multiplier formula (see working paper, section 2.4) that they often mixed up both methods. For instance, following Foville (1893), Colson (1903, vol.2, pp.282-283) presents a census-based estimate of national wealth for 1898, then notes that it is roughly equal to $30-35$ times the inheritance flow, and a few pages later presents national wealth estimates for the 1820s, 1840s, 1860s, 1880s and 1890s based on the estate multiplier method, i.e. by multiplying by 30-35 the inheritance flow. We did not use such estimates.
    ${ }^{100}$ See Colson (1918, livre 2, p.372). See also Divisia, Dupin and Roy (1956, vol.3, p.69), who start their 1954 computations from this 1913 Colson estimate.
    ${ }^{101}$ E.g. Colson provides an estimate of 230 billions for 1898 (see Colson (1903, vol.2, pp.282-283), while Leroy-Beaulieu provides an estimate of 195 billions for 1900 (see Danysz (1934, p.141)).
    ${ }^{102}$ For a compilation of various national wealth estimates from 1800 to 1913, see e.g. Fovile (1893, pp.604605), Danysz (1934,p.141); "Quelques données statistiques sur l'imposition en France des fortunes privées", unsigned article, Bulletin Mensuel de Statistique, Insee, 1958, p.34; and Lévy-Leboyer (1977, p.396).
    ${ }^{103}$ The estimates for government assets and debt reported on Table A16 for the 1820-1880 should be viewed as approximate and illustrative (the corresponding raw estimates are less sophisticated than the Colson-type estimates computed around 1890-1913).
    104 The other asset categories used in these estimates are not sufficiently homogenous through time to produce detailed composition series. Around 1900-1913, the total value of real estate and land was typically about $45 \%-50 \%$ of aggregate private wealth in most estimates (roughly $20 \%-25 \%$ for real estate, and $25 \%$ for land); around 1800-1820, the total value of real estate and land was as large as $65 \%-75 \%$ of aggregate private wealth in most estimates (roughly $20 \%-25 \%$ for real estate, and as much as $45 \%-50 \%$ for land). This appears to be consistent with the decline of the agricultural sector and the rise of the manufacturing and services sector. It is difficult to go much beyond this at this stage, because the frontiers between cultivated land, rural and urban real-estate properties and non-land, non-real-estate tangible business assets are not fully homogenous over time in the raw data coming from the tax administration decennial censuses of

[^98]:    property values (and consequently in the national and private wealth estimates constructed by the economists of the time).
    ${ }_{105}^{105}$ See the raw price index series reported on Tables A20-A22 below.
    ${ }^{106}$ See Colson (1927, pp.484-486). Colson then converted his 1925 private wealth estimates expressed in 1925 asset prices (1060 billions francs) into an estimate expressed in 1913 prices using consumer price inflation between 1913 and 1925 (he assumes consumer prices were multiplied by 4.0 between 1913 and 1925, which is very close to the 4.1 ratio we obtain with our CPI series, see Table A20, col.(1)), and found that 1925 private wealth was equal to 265 billions 1913 francs, i.e. about $10 \%$ less than his 1913 estimate. The subsequent literature usually refers to this 265 billions number (see e.g. Danysz 1934 p. 141 and BMS 1958 p. 34), but it is important to realize that it was computed by Colson using 1925 relative asset prices, not 1913 relative asset prices.
    ${ }^{107}$ We made two important downward corrections to the Colson raw estimate. Fist, for the sake of consistency with modern estimates, we took durable goods and furnitures (20 billions out of the 265 billions

[^99]:    total). Next, although Colson does attempt to use current equity value for publicly traded corporations, it is apparent that he did not make the corresponding correction for private equity and unincorporated businesses: in effect he uses the book value of tangible assets for non-public traded firms, which is problematic at a time when Tobin's $Q$ ratios were probably substantially below $100 \%$. In order to take this into account, we applied a $30 \%$ downward correction to the corresponding values (see excel file for formulas).
    ${ }^{108}$ See Divisia, Dupin and Roy (1956, vol.3, and particularly pp.65-67). More precisely, we used their market value ("valeur vénale") of private wealth of 32000 billions old francs, minus durable goods and furnitures ( 6400 billions), plus net foreign assets ( 500 billions), plus government debt ( 4500 billions), so that $W_{t}=$ 30600 billions old francs (i.e. 47 billions euros). See formulas in the excel file.
    ${ }^{109}$ More precisely, we used the Divisia-Dupin-Roy estimate of 24600 billions old francs of government tangible and financial assets; unfortunately this is a book value estimate ("valeur d'inventaire"; see Divisia et al (1956, p.47)); we converted into a market value by assuming the same market-to-book-value ratio as for private wealth, i.e. we multiplied 24600 by $32000 / 42300$ (this is the "valeur vénale"-"valeur d'inventaire" ratio found by Divisia-Dupin-Roy for private wealth). See formulas in the excel file.

[^100]:    ${ }^{110}$ Expressed in 1913 old francs, total destructions are estimated to 34 billions in 1914-1918 and 61 billions in 1939-1945 (see Divisia et al (1956, pp.62-63)). Physical fights were shorter during World War 2 (there was no fighting in 1941-1943) than during World War 1, but the bombing technology used in 1940 and 1944-1945 was much more devastating than that used during World War 1. Note that these Divisia-Dupin-Roy estimates of total physical destructions during wars (about $10 \%$ of aggregate wealth during World War 1 and about $20 \%$ during World War 2) are much more plausible than the Cornut-Sauvy estimates, according to which as much as one third of the capital stock was destroyed during World War 1, and as much as two thirds during World War 2. We (carelessly) reported these Cornut-Sauvy estimates in our previous work (see Piketty (2001, p.137; 2003, p.1020)). These estimates are dubious, because they are entirely based on estatemultiplied methods, rather than on census-based national wealth estimates, and should therefore be ignored. Cornut (1963, p.399) computed national wealth estimates for 1908, 1934, 1949 and 1954 by multiplying observed fiscal inheritance flows by a sequence of somewhat arbitrary estate multiplier coefficients (Cornut realized that the estate multiplier coefficient should be upgraded over time, but was uncertain as to how this should be done; in the end he picked upgraded coefficients pretty much on a ad hoc basis, or at least with no clear written justification); Sauvy (1984, p.323) then divided these Cornut national wealth estimates by national income estimates, and found wealth-income ratios of $570 \%$ for $1908,350 \%$ for $1934,120 \%$ in 1949 and $140 \%$ in 1953; from which he concluded that the war-induced wealth destruction rate was about one third during World War 1 and two thirds during World War 2. Our new, consistent series show that Sauvy probably underestimates wealth-income ratios in 1908 and 1949-1953 (and overestimates the 1935 ratio). Most importantly, our new series show that wartime physical destructions explain a much smaller fraction of the overall decline in wealth-income ratios than what was implicitly assumed by Sauvy, and that asset price changes played a bigger role. See below.
    ${ }^{111}$ Total foreign assets losses during World War 1 are estimated to as much as $90 \%$ of the 1913 foreign asset portfolio, i.e. about 37 billions francs (see Divisia et al (1956, pp.62-63)). Note that this includes not only foreign asset repudiation (exemplified by the pure case of Russian bonds), but also the loss in foreign asset values due to inflation and stock market collapse. The exact decomposition between wealth destruction via repudiation and wealth destruction via inflation is dfficult to compute, and inrrelevant for our puposes, so we simply add up all foreign asset losses to wartime physical destructions. National income and national wealth data consistently show that foreign assets never recovered from the Wolrd War 1 shock and remained relatively low in the interwar and at the eve of World War 2 (see Tables A5 and A16), so we neglect foreign asset losses during Wolrd War 2.
    ${ }^{112}$ In order to annualize the destruction estimates we assumed that these private wealth destructions could be splitted equally (in real terms, as measured by 1913 consumer prices) over the four years 1915-1918 and over the six years 1940-1945. See the excel file for the resulting raw series (Table A0).

[^101]:    ${ }^{113}$ In particular, it is reinsuring to note that our final estimate for 1954 private wealth ( 30600 billions old francs) turns out to be almost identical to the private wealth estimate given by Masson and Strauss-Kahn (1978, p.38), who find 30700 billions old francs for 1954. Note however that the fact that both estimates turn out to be so close is largely a coincidence, since Masson and Strauss-Kahn use a completely different method: they start from a 1975 estimate of national wealth and work it backwards through savings until 1949; given that they do not take into account capital gains, they should find a smaller number than ours for 1954; the explanation seems to be that on the other hand they underestimate savings with their pre-B2000 national accounts. See also Masson (1986), and Babeau (1983), who uses a similar method. To our knowledge these Masson-Strauss-Kahn-Babeau papers are the only attempt to construct private wealth estimates in France for 1950 s-1960s, i.e. prior to the introduction of official Insee balance sheets in 1970. The only other attempt (based on direct evaluation method close to national wealth accounts) seems to be due to Campion (1971), who gives estimates of total private wealth for 1962 ( 967 billions francs), 1965 ( 1242 billions francs) and 1967 ( 1465 billions francs), which are very close to our estimates (slightly bigger).
    ${ }^{114}$ The $B_{t} / \mathrm{B}_{t}^{\dagger}$ ratio is generally about $110 \%$ both in 1820-1910 and 1980-2010, but is as large as $130 \%-150 \%$ between the 1920s and the 1970s. See Table A4, col. (9). Note also that the $\mathrm{B}_{\mathrm{t}} / \mathrm{B}_{t}{ }^{\dagger}$ ratio reaches $125 \%$ in the 1850 s: it could be because our private wealth estimate for the 1850 s is $10 \%-15 \%$ too high (as compared to other $19^{\text {th }}$ century estimates), and/or because we under-estimate legal estate tax exemptions in this period, and/or because we over-estimate the $\mu_{\mathrm{t}}$ coefficient (see Appendix B).
    ${ }^{115}$ The Cornut-Sauvy wealth-income ratios are as low as $120 \%-140 \%$ in 1949-1953, but this of course is tautological and uninformative, since they were computed by applying estate multiplier coefficients to the fiscal inheritance flow (see above).

[^102]:    ${ }^{116}$ In principle estate tax law always required taxpayers to report market value of assets (at the time of death or gift). In practice, however, it is possible that the tax administration allowed taxpayers to report lower values during times of large inflation, which were numerous during the 1920-1970 period. It is very difficult to estimate the magnitude of this effect, but it can be large. Also, many temporary, asset-specific estate tax exemption regimes were created in the aftermath of both world wars (e.g. for specific public bonds or savings accounts, or for new real estate constructions), and some of them applied for several decades. We attempt to take these into account, but it is possible that we underestimate the fraction of tax exempt assets during this period. The fact that the $B_{t} / B_{t}^{\dagger}$ ratio appears to be almost as large in the 1970 s (when we use official Insee-Banque de France balance sheets) than in the 1920s-1930s and 1950s-1960s (when we rely on Colson-Divisia-Dupin-Roy estimates) suggests that the under-evaluation of the fiscal flow (due to tax evasion and exemption, broadly understood) plays a larger role than the over-evaluation of national wealth in Colson-Divisia-Dupin-Roy estimates (unless the official balance sheets of the 1970s are also over-evaluated).

[^103]:    117 Note that $P_{t+1} / P_{t}$ measures inflation between average consumer prices during year $t$ and average consumer prices during year $t+1$, while $Q_{t+1} / Q_{t}$ measures inflation between asset prices on January $1^{\text {st }}$ of year $t$ and January $1^{\text {st }}$ of year $t+1$. Given our long run focus, this six-month time inconsistency does not really matter (one solution would be to re-compute national wealth accounts in average year prices, but that did not seem worth while).

[^104]:    ${ }^{118}$ Note that in writing equation (A.31) above, we assumed implicitly that savings $S_{t}$ are used to purchase assets at the beginning of year $t$ (i.e. at $Q_{t}$ prices). Taken literally, this assumption does not make much sense, given that production and savings are supposed to take place throughout year t. Again, the consistent way to deal with this would be to re-compute mid-year national wealth estimates, but this did not seem worth while given our long run focus (in order to analyze short term fluctuations, one would need to be more careful about this). One advantage of our modelling is that savings and capital gains enter multiplicatively (rather than additively) into the wealth growth equation (see equation (A.33) below), which facilitates growth decomposition. Had we assumed that savings $\mathrm{S}_{\mathrm{t}}$ were used to purchase assets at the end of year t (i.e. at $Q_{t+1}$ prices), then the accumulation equation would have been: $W_{t+1}=\left(Q_{t+1} / Q_{t}\right) W_{t}+S_{t}$. That is, equation (A.31) would become: $\beta_{t+1}=\beta_{t}\left[1+q_{t+1}+s_{t} / \beta_{t} /\left[1+g_{t+1}\right]\right.$. Equation (A.33) would then be: $1+g_{w t+1}=\left(1+q_{t+1}+g_{w s t+1}\right)$, rather than $1+g_{w+1}=\left(1+q_{t+1}\right)\left(1+g_{w s+1}\right)$. l.e. the equation for total wealth growth would become additive rather than multiplicative. In practice, given that these annual growth rates are usually very small ( $\mathrm{g}_{\text {wst+1 }}$ is typically $1 \%-2 \%$ per year), opting for the multiplicative or additive formulation makes virtually no difference (i.e. capital gains on current-year savings are negligible as compared to both aggregate capital gains and aggregate savings).

[^105]:    119 Note that the detailed balance sheets released by Insee-Banque de France (and available on-line) actually include for each asset category (using ESA 1995 classification codes) the yearly decomposition of asset variation into a saving flow effect and a valuation effect (i.e. an asset specific capital gain). By construction our aggregate real rate of capital gains $q_{t}$ is simply the average Insee-Banque de France valuation effect (weighted over all asset categories), minus CPI inflation.
    ${ }^{120}$ All formulas used to estimate the wealth accumulation equation are available in the excel file.
    ${ }^{121}$ On Table A17 we assumed that the same real rate of capital loss prevailed for $\mathrm{t}=2010$ (i.e. between January $1^{\text {st }} 2009$ and January $1^{\text {st }} 2010$ ) as for $\mathrm{t}=2009$ (i.e. between January $1^{\text {st }} 2008$ and January $1^{\text {st }} 2009$ ).

[^106]:    ${ }^{122}$ The existence of corporate retained earnings is the simplest explanation as to why asset prices might grow structurally faster than consumer prices, thereby generating permanent real capital gains. E.g. in the Gordon-Shapiro equity pricing formula, $Q_{t}=D_{t} /(r-g)$, with $Q_{t}=$ equity price index and $D_{t}=$ dividend flow $)$, dividend payments are supposed to grow at the same rate as national income ( $\left.D_{t}=D_{0} e^{9 t} \& Y_{t}=Y_{0} e^{9 t}\right)$, and the equity price index is also supposed to grow at the same as national income $\left(Q_{t}=Q_{0} e^{\mathrm{gt}}\right)$, thereby generating a permanently positive real rate of capital gains q equal to the real growth rate g. But this can be a steadystate growth path only if the corporate capital stock $\mathrm{K}_{\mathrm{t}}$ also grows at rate g , i.e. if the representative corporation permanently saves and invests a fraction $\mathrm{g} / \mathrm{r}$ of its profits $\pi_{t}=\mathrm{rK}_{\mathrm{t}}=\alpha \mathrm{Y}_{\mathrm{t}}$ as retained earnings (i.e. $\left.\mathrm{E}_{\mathrm{t}}=(\mathrm{g} / \mathrm{r}) \pi_{\mathrm{t}}=\mathrm{g} \mathrm{K}_{\mathrm{t}}\right)$, and distributes a fraction $1-\mathrm{g} / \mathrm{r}$ as dividends (i.e. $\left.\mathrm{D}_{\mathrm{t}}=(1-\mathrm{g} / \mathrm{r}) \pi_{\mathrm{t}}=(\mathrm{r}-\mathrm{g}) \mathrm{K}_{\mathrm{t}}\right)$. In effect the total equity return $r$ is the sum of a dividend yield equal to $r-g$ and of a real capital gain term equals to $g$ generated by retained earnings. Our series show that retained earnings do indeed explain a significant fraction of capital gains, but are too small to generate permanent real capital gains $q$ as large as g . See Gordon (1959) for the original derivation of the formula (Gordon explicitly assumes that companies keep a fraction $\mathrm{g} / \mathrm{r}$ of their profits as retained earnings). See Baker, DeLong and Krugman (2005) for a discussion of how the formula can be used to think about the long term macro relationship between $r$ and $g$.

[^107]:    ${ }^{123}$ With wealth destruction rates $d_{t}$, equation (A.33) simply becomes: $1+g_{w t+1}=\left(1+q_{t+1}\right)\left(1+g_{w s+1}\right)\left(1+d_{t}\right)$. See excel file for simulation formulas.
    ${ }^{124}$ See Table A17, col. (4) vs col. (10). By construction both methods deliver similar results for years 1896, 1913, 1925, 1954 and 1970-2009, and differ only in the relatively short run. To the extent that short-run variations in corporate retained earnings are informative about short run variations in corporate market values, method $\mathrm{n}^{\circ} 1$ delivers more precise series than method $\mathrm{n}^{\circ} 2$. Also, the savings vs capital gains decomposition of wealth accumulation obtained under method $\mathrm{n}^{\circ} 1$ is arguably more consistent from a conceptual viewpoint. But as far as estimating decennial-averages wealth-income and inheritance-income ratios is concerned, the choice between the two series is virtually irrelevant.
    ${ }_{125}$ In the simulation appendix (see Appendix D, Tables D1-D2), we use the results obtained on Table A18 in order to annualize our 1820-1913 series on national income and private wealth.

[^108]:    ${ }^{126}$ The relatively large capital losses of the 1870 s seem to be due the capital shocks incurred by French private wealth holders following the 1870-1 war with Germany. We did not attempt to investigate how much can be accounted for by the large capital payment subsequently made to Germany, vs the annexation of Alsace-Moselle (about 5\% of the French territory, population-wise), vs physical capital destructions due to the war (which appear to be limited). In any case, it is apparent that such $19^{\text {th }}$ century-style conflicts had a limited impact on aggregate wealth accumulation, as compared to the devastating effects of $20^{\text {th }}$ century wars and ensuing government interventions.
    ${ }^{127}$ Taken literally, this would mean that while consumer prices have increased at $0.5 \%$ per year during the 1820-1913, asset prices have increased at 0.5\%-0.1\%=0.4\% per year.
    ${ }^{128}$ We also report on Table A18 (col. (13)-(14)) the raw wage series used to estimate our $19^{\text {th }}$ century capital and labor shares series (see Table A12 above).

[^109]:    ${ }^{129}$ Note that the much higher capital losses estimated over 1913-1925 than over 1925-1954 ( $\mathrm{q}_{\mathrm{t}}=-5.6 \%$ vs $\mathrm{q}_{\mathrm{t}}=-1.2 \%$ ) reflects the fact that the prices of private assets (real estate and equity) lagged behind consumer prices during the first sub-period (possibly because consumer price inflation in 1913-1925 came after a century-long period of almost complete price stability), and the fact that public debt reached very high levels in France in the 1920s (see Table A16 above): private individuals lent a lot of money to the French government during World War 1 and the early 1920s, and suffered enormous implicit capital losses on this investment (the real rate of capital gains $q_{t}$ on nominal assets such as public debt is by definition equal $-p_{t}$ ). We did not attempt to disentangle the shares of each effect.
    ${ }^{130}$ We also have various indexes for total returns on stocks and bonds (see Tables A20-A22). See section A6 below for the various sources where these raw indexes can be found.

[^110]:    ${ }^{131}$ Namely $30 \%$ real estate, $30 \%$ equity, $20 \%$ CPI-type assets (i.e. assets with prices rising like consumer prices), and $20 \%$ nominal assets (i.e. assets with fixed nominal prices like public debt or checking accounts). See Table A21.
    ${ }^{132}$ See Table A22, col. (11) vs col. (14), lines 1896-1913, 1913-1925, 1925-1954 and 1954-1970.
    ${ }^{133}$ Expressed as a fraction of CPI, raw real estate and equity indexes on the early 1950s are worth about $10 \%$ their 1913 value. See Table A20, col. (1)-(4). If we were to use such indexes we would find wealthincome ratios substantially below $200 \%$ in the early 1950s. There are several reasons why these indexes might overstate the 1913-1949 fall in asset prices: Paris housing prices probably fell more than average French housing prices, and there exists no national index before 1936; even after this date it is unclear whether the index relies on a truly representative sample of housing units sales, or whether large cities are oversampled; also, the tough rent control policies applied in the aftermath of world wars led to a dual price system for occupied and non-occupied housing (typically rents can be raised only after a change in tenants, which also explain why rent recovery can span over several decades after the end of rent control), and it is unclear how this was dealt with by sales-based indexes (biases can go both ways); finally, it is likely that the 1913-1949 fall in public equity prices largely overstates the aggregate fall in (public and private) firm value.

[^111]:    ${ }^{134}$ See Table A20, col. (1)-(3). The national real estate index currently looks even bigger (about six-seven times the CPI), but this is simply because it starts in 1936 (at a time when real estate prices were already very low as compared to 1913).
    ${ }^{135}$ One standard reason why existing stock price indexes might rise structurally faster than consumer prices in the long run is of course the existence of corporate retained earnings. Other explanations include a structural rise in the share of the national economy quoted in the stock market (either because of the share of publicly quoted firms in national output rises, or because publicly quoted firms start to rely more on equity finance than on debt finance; such a structural evolution seems to have occurred since the 1970s-1980s) and the rise of cross holdings within the corporate sector (which can create an artificial rise in stock market capitalization, and possibly a rise in stock price indexes, depending on how weights are computed in commonly available stock indexes). Also, because in practice the set of publicly traded firms changes many times over the course of a century, long run stock indexes necessarily rely upon fairly specific assumptions about portfolio reallocation and reweighting; such assumptions are relatively innocuous in the short run, but can have huge effects in the long run.

[^112]:    ${ }^{136}$ Note that our savings-based method implicitly takes quality improvements into account. E.g. if the raw (non-quality-corrected) price of Paris apartments doubles between 1900 and 2000, and if observed savings flows appear to be sufficient to account for the observed doubling of the wealth-income ratio, then it is reasonable to infer that the doubling of the real estate price is entirely due to savings-financed quality improvements in Paris apartments (i.e. savings flows were implicitly used to finance investment in Paris housing so as to improve their quality).
    ${ }^{137}$ We borrowed 1891-1998 annual CPI inflation rates from Piketty (2001, pp.690-691, Table F1, col. (5)). We updated the series by using the latest 1999-2008 CPI inflation rates released on www.insee.fr (15/09/2009). For 2009 we used the latest projections available ( $0.4 \%$ ). For $1800-1890$ we used the consumer price inflation series included in the Friggit data base (see below).
    ${ }^{138}$ The Friggit historical data base (Itseries.v4.0.xls, available on-line, downloaded on 15/09/2009) ends in 2005, so for 2006-2009 we uptaded the Notaries-Insee (BMS) official real estate indexes. This is the same data source as the one used by Friggit for the recent period.
    ${ }^{139}$ For 2006-2009 we updated the historical Friggit series by using the SBF 250 total stock return index released by Euronext.com (15/09/2009); this is the same data source as the one used by Friggit for the recent period. Euronext does not seem to release total bond return indexes, so we updated the Friggit series by assuming $5.0 \%$ returns for 2006-2009 (this is consistent with previous years).
    ${ }^{140}$ Unfortunately the Friggit data base does not include the decomposition of the total stock return index into a pure price index and a dividend index. Euronext series do provide such a breakdown (on average over the 1991-2009 period the total stock return of $6.8 \%$ can be broken down into a $3.8 \%$ price effect and a $3.0 \%$ dividend effect), but do not go beyond 1991. So we used the 1890-1985 equity price index published by Villa (see Villa (1994, p.146, series "Q: Indice du cours des valeurs françaises à revenus variables"), which we complete for 1856-1890 using the equity price index published in AR 1966, Insee, p.541. For 1986-1990 we used Friggit's total return index, minus 3.0\% (i.e. the average dividend yield over 1991-2009).

[^113]:    ${ }^{141}$ The old franc was replaced by the new franc on January $1^{\text {st }} 1960$ ( 1 new franc $=100$ old francs), and the new franc was replaced by the euro on January $1^{\text {st }} 2002$ ( 1 euro $=6.55957$ new francs). In order to convert 1949-2001 current currency values into what we call current euros, we simply divided 1960-2001 new francs values by 6.55957, and 1949-1959 old francs values by 655.957. Current prices national accounts series released by Insee adopt the same monetary convention.

[^114]:    142 "DMTG" stands for "Droits de mutation à titre gratuit" (the official name of the estate tax in France).
    ${ }^{143}$ The aggregate (net wealth)/(gross assets) ratio has varied very little in the long run, from about 93\%-94\% prior to 1914 to about $94 \%-95 \%$ during the interwar period, $96 \%-97 \%$ during the 1950s-1960s and again $94 \%-95 \%$ in the $1980 \mathrm{~s}-2000$ s. I.e. aggregate liabilities have always been around $5 \%$ of aggregate gross assets transmitted at death in France. In the DMTG files, there are very few cases where liabilities exceed assets. In these cases we set net wealth equal to zero (heirs generally choose not to take up such negative bequests). In published Finance Ministry data, bequests with negative net wealth were excluded. Because published net wealth series start in 1903 (prior to the 1901 estate tax reform liabilities were not deductible from gross assets, so we only observe gross assets series in 1826-1902), we assumed a constant (net wealth)/(gross assets) ratio equal to $95 \%$ over the 1826-1913 period, and reduced accordingly the published gross assets series for this period.
    ${ }_{144}$ See "Annuaire statistique de la France 1966, Résumé Rétrospectif", Insee 1966 (thereafter AR 1966), p.530. The numbers reported on col.(1) of Table B1 for 1826-1964 are taken directly from AR 1966 p. 530 . More precisely: for 1826-1913 we took 95\% of col. "Successions - Valeur totale de l'actif brut" (gross assets) (see excel file for formulas and original raw gross assets series); for 1924-1964, we took $100 \%$ of col. "Successions - Valeur totale de l'actif net" (net wealth). For 1921-1922 the bequest flow was not published, so we take the gift flow series, divided by the estimated (gift flow)/(bequest flow) ratio (see below). For 19491959 we divided the raw numbers published in AR 1966 by 655.957, and for 1960-1964 we divided the raw numbers published in AR 1966 by 6.55957 (e.g. in 1964: 8.427 billions francs divided by 6.55957 equals 1.285 billions euros).
    ${ }^{145}$ These quasi-annual 1902-1964 tabulations were used in Piketty (2001, 2003) in order to estimate top estate fractiles using Pareto interpolation techniques. The exact references of the French Finance Ministry statistical bulletins were these tabulations were originally published ("Bulletin de Statistique et de Législation Comparée" (thereafter BSLC) for years 1902-1938, "Bulletin Statistique du Ministère des Finances" (thereafter BSMF) for years 1939-1946, and "Statistiques et Etudes Financières" (thereafter S\&EF) for years 1947-1964) are given in Piketty (2001, Appendix J, p.749). The wealth concept used in these tabulations was net wealth until 1956, and gross assets afterwards (but we know aggregate net wealth from the aggregate AR 1966 series). Note also that the aggregate bequest flow reported in 1902-1956 tabulations is sometime slightly smaller than $100 \%$ of the aggregate bequest flow series published in AR 1966 (e.g. the ratio is about $96 \%-99 \%$ in 1902-1905), which indicates that a small fraction of estate tax returns was not included in size tabulations. For the entire 1826-1964 period we used the AR 1966 series, as explained

[^115]:    above. The French Finance Ministry also compiled tabulations broken down by age of decedents, which we use in section B. 2 below.
    ${ }^{146}$ These rudimentary estate tax statistics are currently published in the «Annuaire Statistique de la DGI» (the yearly statistical publication of the French tax administration, available on-line).
    ${ }^{147}$ In addition to the first DMTG file compiled in 1977, the tax administration and Insee also attempted to link up the income tax returns files compiled in 1975 and 1979 with the bequests and gifts that occurred since 1962 (i.e. since the time annual estate tax tabulations were abandoned by the tax administration). See Canceill (1979) and Lollivier (1986). However these files only cover real estate transmission and include too few annual observations to be of interest for our purposes.
    ${ }^{148}$ See e.g. Arrondel and Laferrère (1992, 1994, 2001) and Arrondel and Masson (2006) for examples of research work using the DMTG files for 1984, 1987, 1994 and 2000.
    ${ }^{149}$ See Laferrère (1990, p.5) and Laferrere and Monteil (1992, p.11): (81/95) x (57.8-9.0)/6.55957 = 6.3 billions $€$. The 81/95 adjustment factor comes from the fact that Fouquet and Meron chose to upgrade the raw fiscal values reported in tax returns by a 95/81 corresponding to their estimated average inflation rate between time of death and year 1977 (see Fouquet and Meron (1982, pp.86-87)), while we choose to use raw fiscal values (see below). The -9.0 term is an estimate of tax exempt assets made by these authors, which we later include (here we look only at the taxable bequest flow).

[^116]:    ${ }^{150}$ See "La repartition des prélèvements obligatoires entre generations et la question de l'équité intergénérationnelle", Rapport du Conseil des Prélèvements Obligatoires, 2008 (thereafter Rapport CPO 2008), p.227. See also «Le patrimoine des ménages », Rapport du Conseil des Prélèvements Obligatoires, 2009 (thereafter Rapport CPO 2009), p. 151.
    ${ }^{151}$ Basic summary statistics extracted from DMTG files have regularly been published in official Finance Ministry reports. See e.g. "L'imposition du capital", Rapport du Conseil des Impôts, 1986, pp.69-83; «L'imposition du patrimoine », Rapport du Conseil des Impôts, 1998, pp.210-211; «Les mutations à titre gratuit », Notes Bleues de Bercy n̊ 148, 2002 ; Rapport CPO 2008 pp. 225-230; Rapport CPO 2009, p. 151. Other extractions from DMTG files are also occasionally published in parliamentary reports. See e.g. "Rapport d'information sur la fiscalité des mutations à titre gratuity", Rapport du Sénat n${ }^{\circ} 65$, 2002 (thereafter Rapport Senat 2002), pp.15-27. The only substantial inconsistency between the numbers reported in these publications and our own estimates is the following: the 2000 aggregate bequest flow published in Rapport CPO 2009 p. 151 ( 34.5 billions $€$ ) is about $10 \%$ lower than our own estimate computed from the 2000 DMTG file ( 38.9 billions $€$ ), and also about $10 \%$ lower than the estimate published in Rapport Senat 2002 p.19. There are other statistical inconsistencies in Rapport CPO 2009, including inconsistencies with the numbers published in Rapport CPO 2008, which provides more complete and reliable tables and should be viewed as the reference source for recent French estate tax statistics.

[^117]:    ${ }^{152}$ For instance, $57.9 \%$ of of estate tax returns filled in 1977 actually correspond to individuals who died in 1977, $26.0 \%$ to individuals who died in 1976, $8.1 \%$ to individuals who died in 1975 and another $8.0 \%$ to individuals who died in 1974 or before (see Fouquet and Méron (1982, p.86)). According to Fouquet-Meron, reported estate values should be increased by as much as $17 \%$ ( $95 / 81$ ) in order to correct this bias and express all values in 1977 prices. In 2006, tax filling delay still seems to be higher than 6 months for a significant proportion of estate tax returns (see Rapport CPO 2008, p.227). However we know very little on average delay prior to 1977, and in order to preserve the continuity of our series it seemed more appropriate to make no adjustment at all.

[^118]:    ${ }^{153}$ See Table B1, col. (8)-(9). The annual number returns reported on col. (8) are taken from published tabulations for 1902-1964, and from DMTG files for 1977-2006. Prior to 1902, the tax administration did not bother collecting data on total numbers of returns. However according to the so-called TRA survey (which follows the estate tax returns of descendents of all couples married in France between 1800 and 1830 and whose family name started with the letters "TRA" up to 1940), the annual number of estate tax returns has been relatively stable around $50 \%-60 \%$ of the annual number of adult decedents throughout the 1820-1910 period (at least as a first approximation). See Bourdieu, Postel-Vinay and Suwa-Eisenmann (2002, 2003). Note that in Paris (where wealth concentration has even been more extreme than in the rest of France at that time), the tax-filing fraction of decedents was as low as $30 \%$ during the 1820-1910 period, before slowly converging towards the national average in the interwar and postwar periods. See Piketty, Postel-Vinay and Rosenthal (2006).
    ${ }^{154}$ It is difficult to know precisely how tax inspectors dealt in practice with successors of decedents with very little wealth. E.g. in case a decedent only leaves low value furniture worth a few months income, are tax inspectors going to chase the children until they fill a return? According to the law, they should: they start from the list of deceased individuals in their city and are supposed to make sure that all transmitted wealth gets recorded. In practice there has probably always been some tolerance with very poor individuals. E.g. the costs of funerals (which for poor individuals often exceed the net estate value) have apparently always been treated as being deductible from the estate (though this is formally not written in the law). The exact effective filling threshold probably varied over time and space. What really matters for our purposes is that given the functioning of the tax administration it has always been impossible to transmit real estate property or non-cash financial assets without filling a return. This is confirmed by the very large tax filers fractions observed throughout this period.
    ${ }^{155}$ See Table B1, col. (8)-(9).
    ${ }_{157}^{156}$ See Table B1, col. (8)-(9).
    157 Annual series on the number of taxable estate tax returns are currently published in the «Annuaire Statistique de la DGI» (see above). Note that non-spouse, non-children heirs are over-represented in

[^119]:    taxable estate tax returns (and in aggregate estate tax receipts): although other heirs (i.e. non-spouse, nonchildren heirs) receive only $15 \%-20 \%$ of the aggregate inheritance flow (see Appendix C, section C.2), they benefit from no or little base exemption (see below), i.e. almost all of them pay positive taxes. Among children heirs, the fraction paying taxes has fluctuated a lot over time, because of large changes in the real value of the children tax exemption (see below). In the 1990s-2000s, it was typically around $5 \%-10 \%$; following the 2007 tax reform (increase in tax exemption thresholds, new rules regarding inter vivos gifts), it could fall below $1 \%-2 \%$, depending on how intensively future decedents use the new legal provisions regarding inter vivos gifts (see below).
    ${ }^{158}$ From a strict legal viewpoint, the threshold introduced in 1956 was actually a tax exemption threshold, not a filling threshold: all estates with gross assets below one million old francs (i.e. 10,000 new francs, i.e. 1,524 euros, at a time when per adult average wealth in current currency was about 2,000 euros; see Appendix A, Table A1, col. (6)) were entirely exempted from estate taxation (no matter who the heirs were); in principle, the universal tax filling obligation was unaffected by this reform; but in practice, tax inspectors received instructions not to chase heirs with gross assets below this threshold, and the (presumably very few) tax returns filled after 1956 with gross assets below 10,000 new francs were entirely excluded from tax publications and statistics. This nominal 10,000 new francs threshold was never updated since 1956 (it simply became 1,500 euros with the 2002 currency change), and it remained until 2004 the only general tax exemption threshold for non-spouse, non-children heirs. In 1960, a tax exemption threshold of 100,000 new francs ( 15,240 euros) was introduced for spouses and children heirs; it was raised to 175,000 francs in 1974, 200,000 francs (175,000 for children) in 1980; 275,000 francs $(250,000)$ in 1981; 300,000 francs $(275,000)$ in 1984; 330,000 francs $(300,000)$ in 1992; 400,000 francs $(300,000)$ in 1999; 500,000 francs $(400,000)$ in 2000; 76,000 euros ( 50,000 for children) in 2005; finally, in 2007, spouses were wholly exempted from estate taxation, and the tax exemption threshold for children heirs was raised to 150,000 euros (with automatic CPI adjustment for subsequent years). An official tax filling threshold of 10,000 euros (in total gross assets) was also introduced in 2004 for spouses and children heirs; this threshold was raised to 50,000 euros in 2006. It does not apply however in case the same heirs benefited from inter vivos gifts from the decedent (in which case all estates must be reported to tax authorities; see below). An official tax filling threshold of 3,000 euros for non-spouse, non-children heirs was introduced in 2004 (not upgraded since then); a tax exemption threshold of 5,000 euros was created in 2006 for brothers/sisters; it was raised to 15,000 euros in 2007, together with the introduction of a 7,500 euros threshold for nephews/nieces.
    ${ }^{159}$ See Appendix A, Table A1, col. (6).

[^120]:    ${ }^{160}$ For the purpose of comparison, note that the estate tax filling threshold in the U.S. was $2,000,000 \$$ (gross assets) in 2008, and that the number of returns was less than $2 \%$ of the total number of adult decedents (less than 40,000 returns, out of a total of 2.5 millions decedents). See IRS estate tax statistics available online. The US estate tax has always been an elite tax since its creation in 1916 (with a tax filers fraction typically less than $2 \%-3 \%$; see Kopczuk-Saez (2004)). It seems unlikely that the French tax filers fraction of decedents drops to such low levels in the foreseeable future.

[^121]:    ${ }^{161}$ Using the raw wealth levels reported by households (with no correction whatsoever) in the wealth surveys conducted by Insee in 1986, 1992, 1998 and 2004 (about 10,000 households per survey), we find a bottom $50 \%$ wealth share of about $7.5 \%$ of aggregate wealth in all three surveys. E.g. in 2004 the average net wealth reported by all households was approximately $200,000 €$, while average wealth reported by the bottom $50 \%$ of the distribution was about $30,000 €$, i.e. $15 \%$ of $200,000 €$. There are good reasons to believe that high-wealth individuals under report their wealth in surveys (omission of various assets such as life insurance, top coding issues, etc.), and the true wealth share of the bottom $50 \%$ is probably closer to $5 \%$ than to $7 \%-8 \%$. If we compute the bottom $50 \%$ share for the various age groups, we find a slightly rising profile (from about 5\% for lower age groups to slightly above $10 \%$ for older age groups), but the pattern is not entirely clear cut, and in any case pretty small.
    ${ }^{162}$ The bottom $50 \%$ wealth share appears to be about $2 \%$ of aggregate wealth in all SCF surveys conducted between 1989 and 2007. See Kennickell (2009, p.35, table 4). Note that the exact figure one obtains for bottom half wealth shares depends on a number of measurement issues, e.g. how one counts negative net wealth individuals. In this research we conventionally set them to zero, since negative net wealth cannot be transmitted (see above). Kennickell also adopts this convention.
    ${ }_{164}^{163}(5 / 0.5) /(95 / 0.5)=5.3 \%$.
    ${ }_{165}^{164}(10 / 0.5) /(90 / 0.5)=11.1 \%$.
    ${ }^{165}$ See Laferrère and Monteil (1994) and Accardo and Monteil (1995). This 1988 "Wealth at death" was carried out jointly by Insee and the tax administration, and its specific purpose was to learn more about the wealth of non-filers decedents. It was based on a representative sample of all adult deceasing in 1988, for which the tax administration gathered not only the estate tax returns of the tax filers subsamble (about $50 \%$ of dedecents at that time), but also all other tax forms available for non tax filers (past income tax and local tax returns, bank forms on assets and asset returns, past bequest and gift tax returns, registration duties for sales of real estate assets, etc.), so as to compute relatively precise estimates of the average non-filers wealth $\mathrm{w}_{\mathrm{nf}}$. They found that the aggregate wealth share of non-filers was about $13 \%$, which corresponds to a $z_{\mathrm{dt}}{ }^{\text {nf }}$ ratio of about $15 \%$ : ( $13 / 0.5$ )/(87/0.5) $=14.9 \%$.

[^122]:    ${ }^{166}$ On the historical evolution of top and middle wealth shares, see working paper, section 7.2, and Piketty, Postel-Vinay and Rosenthal (2006, appendix tables A4 and A7). These top wealth share estimates rely on estate tax data (and crudely estimated aggregate wealth series), so by construction they do not give very precise estimates of the bottom shares. But with top $10 \%$ wealth shares as large as $80 \%-90 \%$ in 1820-1913 and as large as $70 \%-80 \%$ in the interwar period and the 1950s, bottom $50 \%$ wealth shares are bound to be very small, probably less than $5 \%$ (today top decile wealth shares are about $-60 \%$, and bottom $50 \%$ shares are about 5\%-10\%)
    ${ }^{167}$ Comparing the estate-size tabulations for 1950-1955 and 1956-1960 one can approximately compute the average wealth of the non-filers of the second sub-period (who were filers during the first sub-period), and one finds $z_{d t}{ }^{\text {nf }}$ ratios around $5 \%$ (for the raw tabulations, see Piketty (2001, appendix J)). Alternatively, note that the filers fraction of decedents was about $20 \%$ in the late 1950 s, and that the top $20 \%$ wealth share was approximately $80 \%-85 \%$ at that time (see Piketty et al (2006, appendix table A7)); if one assumes that the non-filers were the bottom $80 \%$ of the distribution, then one again finds a bottom-top wealth ratio $z_{d t}{ }^{\text {nf }}$ around $5 \%:(15 / 0.8) /(85 / 0.2)=4.4 \%$, and $(20 / 0.8) /(80 / 0.2)=6.3 \%$.
    168 Our annual series on tax filers fractions $\mathrm{n}_{\mathrm{dt}}{ }^{\dagger}$ start in 1902 , but we know that the filers fraction was approximately stable during the $19^{\text {th }}$ century (see above), so we assume that $n_{d t}{ }^{\text {f }}$ was the same in 1826-1901 as in 1902 (see formulas in excel file).

[^123]:    ${ }^{169}$ Using 1984-2000 DMTG micro files we obtained the following break down for the aggregate bequest flow. The share of residential real estate went from $44 \%$ of total gross assets in $1984,47 \%$ in $1987,42 \%$ in 1994 and $39 \%$ in 2000. The share of non-housing tangible assets went from $13 \%$ of total gross assets in 1984 to $9 \%$ in $1987,6 \%$ in 1994 and $4 \%$ in 2000. The share of financial assets (including private equity) went from $44 \%$ of total gross assets in 1984 to $44 \%$ in $1987,51 \%$ in 1994 and $57 \%$ in 2000 . The share of financial liabilities went from 5\% of total gross assets in 1984 to $7 \%$ in $1987,5 \%$ in 1994, and $5 \%$ in 2000 . Note that these series cannot easily be broken down in a more detailed manner, because asset categories used in DMTG files are not fully homogenous over time.
    ${ }^{170}$ These estimated fractions are reported on Table A15b.
    ${ }^{171}$ This $20 \%$ tax exemption coefficient might be somewhat underestimated, especially at the beginning of the 1970-2009 period. First, housing assets currently benefit from a $20 \%$ rebate on market values whenever the asset serves as the primary residence of the decedent and the surviving spouse, or of the decedent and one of the children. In DMTG micro files we do not know how often this rebate is used (reported values are afterrebate values, if applicable), but this is probably a very large fraction. Next, in order to foster reconstruction a general estate tax exemption was introduced in 1947 for the first intergenerational transmission of all real estate properties built between 1947 and 1973. According to some estimates, the loss in estate tax revenues due to this specific exemption was as large as $25 \%$ in the 1970s (see Rapport du Conseil des Impôts, 1986, p.44). See also Laferrère (1990, p.5), who on the basis of the DMTG 1977 micro-file estimates that this specific exemption accounts for an aggregate loss in bequest tax base as large as $20 \%$.
    ${ }^{172}$ Family firms have always benefited from various exemptions and special tax rebates, whether they take the form of unincorporated businesses (e.g. commercial dwellings or agricultural assets directly owned by self-employed individuals) or the form of corporate unquoted firms (private equity financial assets). The rules required to qualify for the "biens professionnels" tax rebates have been repeatedly relaxed in the 1990s2000s (e.g. currently successors only need to commit to operate the family business for two years after the decedent passed way in order to obtain a $100 \%$ tax rebate, with no ceiling). We did not attempt to enter into the complicated history of these special exemptions (for more details, see e.g. Rapport CPO 2008 and 2009). Given the very low levels of business assets reported in estate tax returns (see above), our estimated $30 \%$ tax exempt fraction for non-housing tangible business assets and $50 \%$ tax exempt fraction for private equity appear to be reasonable (and probably slightly under-estimated at the end of the 1970-2009 period).

[^124]:    ${ }_{180}^{179}$ See working paper, section 3.3.
    ${ }^{180}$ In our methodology, the gap between our economic and fiscal inheritance flows can be interpreted as an indirect measure of tax evasion. From that perspective, tax evasion would appear to be trendless in the long run: in particular the gap between the two series does not seem to increase after 1984 (see working paper, Figures 1 and 2). However the gap between the two series also reflects all other measurement errors, so it is hard to reach precise conclusions about tax evasion from this kind of comparison (apart from the fact that it does not seem to affect long run patterns).
    ${ }^{181}$ See AR 1966, p.530. Here we look at the ratio between the sum of all taxable and tax-exempt gross assets (i.e. "valeurs soumises ou non aux droits", defined as the sum of "valeurs mobilières - fonds d'Etat, actions, obligations", "autres biens meubles", "biens immeubles urbains et ruraux") and the value of taxable gross assets ("valeur total de l'actif brut"). The tax administration started compiling estimates on tax exempt assets only in 1898; until 1897 the tax administration asset composition series solely refer to taxable assets; so by construction this ratio is equal to $100 \%$ over the $1826-1897$ period. The ratio is always above $100 \%$ over the 1898-1964 period and offers the best available estimate of tax exempt assets for this period. Note however that this ratio displays intriguing variations around World War 2, e.g. it is as high as $140 \%$ in 1943 and 1949, while it is about $120 \%-125 \%$ for all surrounding years; it is possible that for these years the tax administration wrongly included into tax exempt assets the fraction of community assets belonging to surviving spouses; this would need to be further investigated; we neglected these high ratios and assumed that tax exempt assets were a constant $20 \%$ fraction of total assets over the 1910-1950 period; but it is possible that by doing so we under-estimate somewhat the importance of tax exempt assets in the 1940s. Note also that according to these asset composition series the overall fraction of real estate (urban and rural properties, including land values) in the aggregate bequest flow gradually declined from as much as $60 \%$ $70 \%$ in the 1820s to about $50 \%$ around 1900-1910, which is consistent with the evolution of asset composition observed in national wealth estimates (see Appendix A, section A.5).
    ${ }^{182}$ That is, we assumed that the ratio ( $\left.\mathrm{B}_{\mathrm{t}}^{\mathrm{t2}}-\mathrm{B}_{\mathrm{t}}^{\mathrm{f1}}\right) / \mathrm{B}_{\mathrm{t}}^{12}$ was rose from $5 \%$ in 1900 to $20 \%$ in 1910 (using Finance Ministry ratios), then stabilized at $20 \%$ in 1910-1950, then rose linearly from $20 \%$ in 1950 to our estimate of about $25 \%$ in 1970 (see formula for col. (7) of Table B1 in excel file). The 1950-1970 rise if consistent with the development of new exemption regimes for specific housing and public bonds assets during this period (see above).

[^125]:    ${ }^{183}$ See Appendix A, section A.5.
    ${ }^{184}$ For simplicity we again assumed linear trends. See Table B1, col. (7).
    ${ }^{185}$ In the simulations, we re-attribute gifts to the proper generation of decedents. See Appendix D.
    ${ }^{186}$ Regarding tax exempt assets, the same rules apply to bequests and gifts, so it makes sense to assume the same correction factor (though the 1977 estimates published by Laférère (1990, p.5) suggest a significantly larger fraction of tax exempt assets for gifts than for bequests; unfortunately we do not have similar estimates for other years, so we decided that it was more reasonable to keep the same correction for bequests and gifts for the entire period under study). Regarding non filers, note that there has never been any official filling threshold for inter vivos gifts: in principle, from 1791 up until the present day, all gifts are supposed to be reported to tax authorities in France, no matter how small they are (otherwise individuals could just fractionalize gifts indefinitely and transmit large wealth levels entirely tax free). In practice however, according to French case law, it is of course allowed to make birthday presents and other "small gifts" (as long as they are of "reasonable" value, which according to case law should be interpreted as varying with the living standards of the donor, among other things) without reporting them to tax authorities. It is likely that many not-so-small gifts never get reported, so that the true non-filers upgrade factor is probably larger for gifts than for bequests.

[^126]:    ${ }^{187}$ For 1826-1964, we simply reported on col. (8) of Table A1 the raw gift flow series published in AR 1966, p.530, col. "Donations". Note that the Finance Ministry sadly did not compile gift flow series for years 19231943 (i.e. the annual 1826-1964 series published in AR 1966 p. 530 display years 1923-1943 as missing years, and the Finance Ministry publications of the interwar period do not provide any gift data either). Since the gift-bequest ratio appears to be relatively stable around $20 \%-30 \%$ both in the 1870s-1910s and in the 1940s-1970s, we simply assumed a $25 \%$ ratio for the 1920s-1930s (see col. (9), Table B1). Gift tax receipts vs bequest tax receipts series (which are available on an annual basis since the 1820s up until today, and in particular are available for the interwar period) seem to be consistent with this approximate assumption (because of tax progressivity, it is unfortunately difficult to obtain precise tax base estimates from tax receipts series, particularly for the interwar period). The gift flow data published for 1921-1922, as compared to the bequest flow data published after 1925, suggests that the gift-bequest ratio was closer to $25 \%$ than to $20 \%$ during the interwar period (i.e. was intermediate between pre World War 1 and post World War 2 levels).
    ${ }^{188}$ For 1984-2000 we report gift flow estimates coming from our own computations using DMTG micro-files. The series we obtain, and the corresponding evolution of the $v_{t}$ ratio, are similar to those published in various official reports. See e.g. Rapport du Conseil des Impôts, 1998, pp.210-211, for gift and bequest flows similar to ours (corresponding to $\mathrm{v}_{\mathrm{t}}=29 \%$ in 1984 and $\mathrm{v}_{\mathrm{t}}=64 \%$ in 1994). For 2006, we take the estimates published in Rapport CPO 2008: $\mathrm{V}_{\mathrm{t}}^{\text {f0 }}=48.0$ billions was computed as the sum of the regular gift flow ( 39.4 billions) (see Rapport CPO 2008 p.273) and the average yearly 2004-2006 flow under the special cash-gifts regime ( 8.6 billions) (see CPO 2008 p.241; apparently this extra flow was not included in the regular flow statistics; if we were to exclude it, we would find $\mathrm{v}_{\mathrm{t}}=67 \%$ rather than $\mathrm{v}_{\mathrm{t}}=82 \%$, which would still be high by historical standards; given the regular flow $\mathrm{v}_{\mathrm{t}}=81 \%$ obtained in the DMTG 2000 micro file, at a time when there was no such special regime, it seems more justified to look at the full flow in 2006). For 1977, the gift and bequest flow estimates computed by Laferrère (1990, p.5) correspond to a gift-bequest ratio $\mathrm{v}_{\mathrm{t}}=49 \%$ ( $=(37.7-$ 14)/(57.8-9)). However this does not seem fully consistent with the gift tax receipts vs bequest tax receipts series, which suggest that the gift-bequest ratio in the 1970s was similar to the levels observed in the 1964 and in 1984 (i.e. $\mathrm{v}_{\mathrm{t}}=25 \%-30 \%$ ). So we did not use this 1977 gift estimate and instead assumed that the ratio $\mathrm{v}_{\mathrm{t}}$ evolved linearly between 1964 and 1984 (see Table B1, col. (10)). This would need to be further investigated.
    ${ }^{189}$ In 2006 the Finance Ministry started to computerize all gift tax returns on an annual basis, so in principle data quality should improve soon. So far this however does not apply to bequest tax returns.
    ${ }^{190}$ We need annual series on the gift-bequest ratio $v_{t}$ for the economic inheritance flow computation (see Appendix A, section A2), which we obtained by simple linear interpolation (see Table B1, col. (9)). Given the data at our disposable, this looks like the most reasonable approximation.

[^127]:    ${ }^{191}$ In addition the tax rates themselves differed: between 1901 and 1942, bequests were subject to graduated tax schedules, while gifts were subject to quasi-proportional tax rates (always varying with the identity of the donee).
    ${ }^{192}$ The tax paid at the time of the gift is deducted from the tax liability computed at the time of death on the sum of gift and bequest. I.e. if $t($.$) is the relevant tax schedule, v$ is the gift and $b$ is the bequest, then one pays tax $t(v)$ at the time of the gift, and $t(b+v)-t(v)$ at the time of death, so that the total tax payment is $t(b+v)$, independently of the b vs v split, for given $\mathrm{b}+\mathrm{v}$. Note that although so-called "recalled gifts" ("donations rappelées") play an important role for tax computation, they are never included in the Finance Ministry estate tax statistics we used (i.e. the tax administration always compiled separate statistical tables for bequests and gifts, both before and after 1942). The bequest flow reported on col. (1) of Table B1 is the bequest flow strictly speaking, excluding recalled gifts ("hors donations rappelées"). In 1977-2006 DMTG micro-files, we do observe all variables necessary to reproduce the tax computations, and in particular we observed recalled gifts (together with the year of gifts), but we did not add them to the bequest flow. We did check though the reported recalled gifts are consistent with observed past gift flows (given mortality rates and other special rules applying to gifts, see below); they are consistent, i.e. the system seems to be applied relatively strictly.
    ${ }^{193}$ Also, note that within the realm of the 1942 law, donors can choose (but are not obliged) to pay the gift tax in place of the donee, and this tax giff $t(v)$ is not recalled at the time of death (but is deducted from the tax $t(b+v)$ paid by the heir). For large estates and high tax rates, this can be significant.

[^128]:    ${ }^{194}$ The exact parameters have changed a lot. In 1987-1996, "sharing gifts" made by donors aged less than 65 benefited from a $25 \%$ tax rebate, and those made under age 75 had a $15 \%$ tax rebate. These same rules were extended to all inter vivos gifts in 1996; the $25 \% / 15 \%$ rates became $50 \% / 30 \%$ in 1998 ; they still apply today, except that the age limits are now $70 / 80$ rather than 65/75.
    ${ }^{195}$ In 1998-2001 a general tax rebate of $30 \%$ was applied to all gifts (with no age condition). This was reiterated in 2003-2005 (with a $50 \%$ tax rebate, again with no age condition). In addition, a new special regime for cash gifts below $30,000 €$ given to children and grand-children was applied in 2004-2006 (full tax exemption); this special regime was made permanent in 2007 (but with an age condition: the donor needs to be less than 65 -year-old). These frequent changes in tax incentives have generated significant short-run variations in the volume of gifts, as one might expect, and as one can see from annual gift tax receipts series (see Rapport CPO 2008, pp.240-242). Similar phenomena already occurred in the past (e.g. gift tax receipts rise in 1981, prior to the repeal of the sharing gifts regime and the creation of the wealth tax). Generally speaking, gift flows are structurally more volatile than bequest flows, and one must be careful when using non-annual gift series (which can easily be contaminated by purely temporary, tax-induced variations). Our 1964-1984-1987-1994-2000-2006 aggregate gift flow estimates appear however to be representative of the long run tendency (i.e. by using gift tax receipts annual series we did our best to ensure that these are not particularly high $v_{t}$ or low $v_{t}$ years; e.g. we smoothed over three years the large extra flow generated by the cash-gifts special regime in 2004-2006, see above), to the extent of course that there exists a long run tendency (see below the discussion on the long run sustainability of high $\mathrm{v}_{\mathrm{t}}$ ratios).
    ${ }^{196}$ Together with the 2007 increase in the tax exemption threshold (from $50,000 €$ to $150,000 €$ per children, see above), this implies that one can now transmit relatively large estates to children without paying any tax, assuming one starts making gifts sufficiently early. The way the "x year rule" works is indeed that one can in effect benefits from the base exemption every x years. So, to consider an extreme case, under the " 6 year rule", by starting making gifts at age 50 a parent dying at age 80 can now transmit six times $150,000 €$ tax free to a given children, i.e. $900,000 €$. Each parent can do that with each children, so in effect a sufficiently forward looking (and tax-phobic) married couple with two children can transmit 3.6 millions $€$ tax free to its children. This is comparable to the base exemption threshold currently applied in the U.S. (2 million $\$$ in 2008, for each parent), but requires relatively sophisticated behaviour, and high parental willingness to give away assets relatively early in life. This new legal regime has been applied only since September 2007, and it will take several decades (and much better data than that currently available) before one can estimate its full long run effects.

[^129]:    ${ }_{198}^{197}$ See Table B6 below or Appendix C...
    ${ }^{198}$ Of course with annuitized wealth the average wealth of decedents of age a (right before death) and the average estate left by decedents of age a (right after death) could differ, and so would the age profiles. However the fraction of annuitized wealth is very small in France, and this can be ignored here. On this issue, see Appendix A, section A5.

[^130]:    ${ }^{199}$ The DMTG 1977 age table published by Fouquet and Meron (1982, p.88) only reports the number of estate tax returns by age bracket (not the value of these estates), which is insufficient to reliably estimate the age-wealth profile.
    ${ }^{200}$ Note that the "raw" age-wealth profiles reported on Table B3 all include a correction for non-filers (see below). For 1984-2000, we report profiles coming from our own computations using DMTG micro-files. For 2006, we use the age table (indicating numbers and values of estates by age bracket) computed from the DMTG 2006 survey and published in Rapport CPO 2008, p.251. Note that this table actually reports average individual bequest shares ("parts successorales moyennes") by age-of-decedent brackets (rather than average estate). To the extent that the average number of successors rises with decedent age (which we observe for other years), this suggests that we under-estimate somewhat the steepness of the 2006 agewealth profile (and hence the $\mu_{\mathrm{t}}$ ratio in 2006).

[^131]:    ${ }^{201}$ Tables broken down by age brackets compiled during the 1943-1964 period were published in the same statistical bulletins (BSLC, BSMF and S\&EF) as the tables broken down by estate brackets. See Piketty (2001, Appendix J, p.749) for exact references. Just like the estate-bracket tables, these age-bracket tables were also compiled and published at the department-level (not only at the national level). Between 1943 and 1954, the tax administration also compiled and published cross tabulations indicating the number and values of estates broken down by estate and age cross brackets.
    ${ }^{202}$ The 1906-1908-1928-1934 age tables were published in the same BSLC bulletins as other tables.
    ${ }^{203}$ Around 1890-1930, the Paris share in the aggregate national bequest flow was over $25 \%$. Earlier in the $19^{\text {th }}$ century, it was about $15 \%-20 \%$. See Piketty et al (2006, table 1, p.240).
    ${ }^{204}$ The 1943-1964 age-bracket tables compiled by the tax administration were also compiled and published at the department-level (about 90 departments in France, including Paris) (see above). The 1977-2006 DMTG micro samples are too small in size to compute reliable department-level age tables, but sufficiently large to compare Paris profiles with France-minus-Paris profiles, which we did with the 1984-2000 microfiles.

[^132]:    ${ }^{205}$ The full results of this 1931 special survey were published by Danysz (1934).
    ${ }^{206}$ The raw Paris profiles (see Piketty et al (2006, table 5, p.253)) display the same evolution as the national profiles reported on Table B3 for the 1890-1930 period, except that they are always more steeply upward sloping. E.g. around 1890-1910, we estimate that $\mathrm{w}_{\mathrm{dt}}^{80-89}$ was about $200 \%-250 \%$ of $\mathrm{w}_{\mathrm{dt}}^{50-59}$ for the whole of France, vs as much as $350 \%-400 \%$ in Paris; in the $1920 \mathrm{~s}-1930 \mathrm{~s}$, we estimate that $\mathrm{w}_{\mathrm{dt}}^{80-89}$ was about $150 \%-$ $180 \%$ of $\mathrm{w}_{\mathrm{dt}}^{50-59}$ for the whole of France, vs $200 \%-300 \%$ in Paris. The steeper Paris profiles reflect the extremely high level of wealth concentration prevailing in Paris at that time, and the fact that most top wealth holders were very old (see Piketty et al (2006)).
    ${ }^{207}$ Namely, housing tax tabulations (which are available for Paris and France throughout the $19^{\text {th }}$ century) and the TRA survey (which includes representative samples of estate tax returns for the all of France starting in the 1820s). Note that the survey suffers from insufficient sample size to properly measure top estates, but is reliable for over $90 \%$ of the population; it offers an imperfect but useful source to evaluate how the gap between the Paris wealth structure and the France-minus-Paris wealth structure has evolved over the $19^{\text {th }}$ century. See Piketty et al (2006, pp.248-249).
    ${ }^{208}$ In particular, the fact that the age-wealth profile gradually became more steeply upward sloping between the 1820s-1850s and the 1870s-1880s (with a corresponding rise in the $\mu_{\mathrm{t}}$ ratio) seems to be extremely robust. Note that according to our computations the age-wealth profile was actually more steeply rising in the whole of France than in Paris in the early $19^{\text {th }}$ century (while the opposite occurs in the late $19^{\text {th }}$ century and in the $20^{\text {th }}$ century). E.g. the raw Paris profiles even show hump shaped profiles in 1817 and 1827 (with $\mathrm{w}_{\mathrm{dt}}^{70-}$ ${ }^{79}$ and $\mathrm{w}_{\mathrm{dt}}{ }^{80-89}$ around $60 \%-90 \%$ of $\mathrm{w}_{\mathrm{dt}}{ }^{50-59} 1817$ and 1827; the Paris profiles then take the standard upward sloping shape from the 1830s onwards; see Piketty et al (2006, table 5, p.253)), while our national estimates show upward-sloping profiles from the 1820s towards. This is consistent with the view that old, wealthy Parisians were hit by strong negative shocks during the Revolutionary years, while in the rest of France the old and wealthy were hit by less strong shocks. However, given the data limitations we face, it is certainly possible that we over-estimate somewhat the steepness of the national age-wealth profile in the 1820s1830s (i.e. that the old of the 1820s-1830s were somewhat poorer than what it suggested on Table B3).

[^133]:    ${ }^{209}$ In the data reported in Piketty et al (2006, table 5, p.253), we forgot to make this correction for year 1994. As a consequence, the reported national profile does not look as upward sloping as it is really (the reported profile even looked - wrongly - slightly hump shaped at high ages). Also, for year 1947, we wrongly reported the Paris profile (in spite of the fact that we refer to it as the national profile), which was at that time slightly upward sloping (while the national profile was hump shaped). For consistent national age-wealth profiles, one should use the new, revised estimates reported on Table B3 of the present paper rather than the estimates reported in Piketty et al (2006) for 1947 and 1994 (the 1807-1902 Paris profiles reported in this paper are correct, though).
    ${ }^{210}$ We performed several alternative computations with $z_{d t}{ }^{\text {nf }}$ varying in the $5 \%-15 \%$ range (and varying with age), and the resulting impact on the level and pattern of $\mu_{t}$ ratios was less than $1 \%$.

[^134]:    ${ }^{211}$ E.g. in the immediate postwar period, when the pattern of average wealth $\mathrm{w}_{\mathrm{dt}}{ }^{\mathrm{f}}(\mathrm{a})$ reported to the tax administration is hump shaped, the pattern of tax filers fractions $\mathrm{n}_{\mathrm{dt}}{ }^{\dagger}(\mathrm{a})$ is also hump shaped (the very old more often with wealth so small that it does not get reported), thereby making the pattern of $\mathrm{w}_{\mathrm{dt}}(\mathrm{a})$ (which we report on Table B3) even more hump-shaped.
    ${ }^{212}$ Because $N_{d t}{ }^{f}(a)$ is usually extremely small for age groups $0-9$ and $10-19$, the corresponding average wealth $w_{d t}{ }^{\dagger}(a)$ can be very volatile across years (especially with the DMTG samples). So the $w_{d t}(a)$ estimates reported on Table B3 for age groups 0-9 and 10-19 are based upon approximate moving averages (e.g. for 1984-2006 we report the averages obtained for all years 1984-2006). We checked in the simulated model that these young-age $\mathrm{w}_{\mathrm{dt}}(\mathrm{a})$ estimates were consistent with the observed patterns of parental age at death and children age at parental death over the entire 1820-2006 period; they are consistent, in the sense that the relative wealth that we attribute to children for various time periods (e.g. during the $19^{\text {th }}$ century) is approximately equal to what they should own according to the simulation model (see Appendix C and D).
    ${ }^{213}$ See formulas in the excel file.

[^135]:    ${ }^{214}$ As was already discussed (see section B1 above), the bottom $50 \%$ wealth share probably rose somewhat in the long run (say, from less than $5 \%$ in the $19^{\text {th }}$ century early $20^{\text {th }}$ century to about $5 \%-10 \%$ today), and it also rises slightly with age (within the $5 \%-15 \%$ range). These are relatively small variations, however, on which we do not have very good data, so we thought it was clearer to make this simplifying assumption ( $\mathrm{s}_{\mathrm{t}}^{\mathrm{P}}(\mathrm{a})=10 \%$ for all years and age groups). We checked that the resulting $\mu_{\mathrm{t}}$ ratio estimates are very robust with respect changes in the assumed patterns $s_{t}{ }^{P}(a)$. E.g. if one assumes that $s_{t}{ }^{P}(a)$ rises over time and/or with age (within the $5 \%-15 \%$ range), then the pattern of $\mu_{\mathrm{t}}$ ratios hardly changes, as one can check by changing the parameters in the corresponding excel file.

[^136]:    ${ }^{215}$ See e.g. Kopczuk and Saez (2004), who carefully review the evidence, and adopt the following age profile of differential mortality: they assume that the ratio between the mortality rate of the rich and the aggregate mortality rate is equal to about $60 \%-70 \%$ below age 50 , up to about $80 \%-90 \%$ at age 70 and $100 \%$ above age 90 (see Kopczuk-Saez, 2004, working paper version, pp.37-39 and Figure A4). This is very close to the profile adopted here (see Table B4).
    ${ }_{216}$ See Attanasio and Hoynes (2000, p.9, table 4). They find that the ratio between the bottom quartile mortality rate and the other three quartiles mortality rate can be as high as $200 \%-300 \%$ at low age (below $50-60$ ), and then declines towards $150 \%$ at higher ages ( $70-80$ ). Within the top three quartiles, differential mortality seems to be more limited (gaps are usually not significant). If one computes the ratio between the bottom half and upper half mortality rates from these Attanasio-Hoynes results, one finds the pattern reported on Table B4 (i.e. from $200 \%$ below age 50 to $110 \%-130 \%$ at age $70-80$ ).

[^137]:    ${ }^{217}$ See appendix do-file domortadiff.txt.
    ${ }^{218}$ See Appendix C, Table C7, col. (1)-(3). The age-at-death gap between the rich and the average seems to be somewhat lower in the mid $20^{\text {th }}$ century (as little as $0.5-1$ years) than at the beginning and at the end of the century ( $2-2.5$ years). Note however the average ages for tax filers were computed using the Finance Ministry tables with decennial age brackets, and are therefore not very precise. Note also the abnormally high age gap of 4 years in 1943: this is clearly due to the abnormally high number of relatively young age decedents in this year (most of which did not file a tax return). All average ages reported on Table C7 of course solely refer to adult decedents (20-year-old and over).

[^138]:    ${ }^{219}$ See excel file for formulas.
    ${ }^{220}$ An alternative strategy would have been to forget about children wealth altogether (and to attribute to adults the small share of national wealth owned by children in the real world). However in our simulations we do model explicitly the full age structure of decedents and heirs (see Appendices $C$ and $D$ ), and it would have been somewhat arbitrary to truncate distributions of heirs age at 20.

[^139]:    ${ }^{221}$ See formulas in excel file.

[^140]:    ${ }^{222}$ In the same way as in Appendix $A$ and $B$, the decennial averages reported on Table C2 refer to years 1820-1829 for "1820", 1830-1939 for "1830". The only exceptions are the 1910s (we took the average of years 1910-1913) and the 1940s (we took the average of years 1946-1949): excluding war years clarifies long run evolutions of demographic ratios (particularly mortality rates). Of course in all annual series and in the simulated annual models, we use all yearly data, including war years.

[^141]:    ${ }^{223}$ See e.g. "La situation démographique en 2007" (Insee-Résultats août 2008, Société n${ }^{\circ} 84$, C. Beaumel and M. Vatan, www.insee.fr). The relevant table for the age structure of the living population $\left(N_{t}=\sum_{x<t} N_{t}^{x}=\right.$

[^142]:    ${ }^{228}$ See "Projections de population active pour la France métropolitaine 2006-2050" (Insee-Résultats avril 2007, Société $n^{\circ} 63$, www.insee.fr). Note that these projections take into account the higher-than-expected fertility figures observed since 2001, and were therefore revised upwards as compared to the previous population projections published in 2001.
    ${ }^{229}$ See www.insee.fr and www.ined.fr.
    ${ }^{230}$ More precisely: the 2008-2050 projections published in 2007 used 2005 as a base year and underestimated somewhat base year population, so that total living population on $1 / 12007$ is equal to 61.365949 millions according to the projections series, vs 61.538322 millions according to the latest Insee estimates. In order to ensure full continuity, we therefore multiplied all 2008-2050 projected series by a uniform factor equal to $1.00281=61.535322 / 61.365949$ (i.e. projections series were upgraded by $0.281 \%$ ).

[^143]:    ${ }^{231}$ We started from an estimate of the age structure of the 1820 population computed from the survival tables published in AR 1966 pp.80-81. We used the 1820-1900 series on annual numbers of births published in AR 1966 pp.66-69. We used the age-level mortality rates observed in 1900-1910 and assumed that each age-level mortality rate followed the same linear evolution during the 1820-1900 period as the five-year-age-group-level mortality rates published in AR 1966 p. 77 . Starting with the 1851 census, we have detailed agegroup data (see AR 1966 p.43), and we find that our date base replicates very well this observed data. See do-file dopopulation18202100.txt.

[^144]:    ${ }^{232}$ This data is taken from F. Daguet, "Un siècle de fécondité française, Caractéristiques et évolution de la fécondité de 1901 à 1999", INSEE-Résultats, 2002, Societe $\mathrm{n}^{\circ} 8$ (updated version available at www.insee.fr), table 1. Note that on table C5 age at birth of children is defined as the generational diffence (i.e. children birth year minus parental birth year). The average age at parenthood has actually been following a slight U shaped curve in the long-run: both men and women had children slightly earlier in life at mid $20^{\text {th }}$ century than in the early $20^{\text {th }}$ century and early $21^{\text {st }}$ century.
    ${ }^{233}$ See F. Daguet, op.cit., table 4.4.
    ${ }^{234}$ Strictly speaking, the Insee data (Daguet, op.cit., table 4.4) provides complete age-level fertility data only for female cohorts born between 1885 and 1955. However assuming stationary evolutions of age-level fertility rates one can use this data to compute average age at parenthood for female cohorts born between 1870 and 1980. For cohorts born before 1870 we assumed that the average age at parenthood was the same as for cohort 1870; for cohorts born after 1980 we assumed that the average age at parenthood was the same as for cohort 1980 .
    ${ }^{235}$ See F. Daguet, op.cit., table 2.2.
    ${ }^{236}$ Note that on table C6 average age of decedents and heirs is defined in the usual way, i.e. $a=t-x-1$. The detailed computations leading to tables C 5 and C 6 are provided in do-files dotableC5.tx and dotableC6.txt.
    ${ }^{237}$ The average age of children heirs that we obtain by using 1984-2000 DMTG micro-files are slightly higher (about 0.5-1 year higher) than those reported on table C6 (col.(4)), which corresponds to the fact that the average age of decedents with estate tax returns is slightly higher than the average age of all decedents (see Table C7). We did not attempt to correct for this.

[^145]:    ${ }^{238}$ We define "other heirs" as all non-children, non-surviving spouse heirs. In practice, these are mostly brothers/sisters and nephews/nieces.
    ${ }^{239}$ Note that the proportion of spouses in the total number of heirs (about $15 \%$ ) is typically larger than the share of spouses in the aggregate inheritance flow (about 10\%); this corresponds to the fact that the average bequest received by spouses is typically lower than that received by children. Note also that the share of spouses in the aggregate inheritance flow seems to have been somewhat larger at mid-century than at both extremes of the $20^{\text {th }}$ century. The "children vs spouses vs others" decomposition of the inheritance flow was $72 \%-10 \%-19 \%$ in 1902 (using data from BSLC oct. 1903 tome 5 p.38), $70 \%-16 \%-14 \%$ in 1962 (using data from S\&EF dec. 1965 supp. $n^{\circ} 204$ pp.1696-1697), and 68\%-11\%-21\% in 2000 (using the DMTG 2000 microfile). Given our aggregate perspective in this paper, it did not seem worth trying to take into account such time variations, and we chose to simplify matters by assuming a constant $70 \%-10 \%-20 \%$ sharing rule (we redid all simulations using a $70 \%-15 \%-15 \%$ constant sharing rule, and no result was significantly affected). It would be interesting however to explore this spouse issue in more details in the future.
    ${ }^{240}$ Note that 7 years is the average age gap between the average age of all decedents (including those with no surviving spouses) and the average age of surviving spouses. This 7 -year gap can be decomposed between a 4.5 -year gap between the average age of decedents and the average age of decedents with surviving spouses (who unsurprisingly tend to be younger than average) an a 2.5 -year gap between those decedents and their surviving spouse.
    ${ }^{241}$ Except for the slight bias described above. Note that the estimates reported on table C5 are also fully consistent with the 1984-2006 estimates of average age of children heirs and all heirs recently published by

[^146]:    the tax administration (see Rapport 2008 du Conseil des Prélèvements Obligatoires, nov.2008, p.279). The tax administration estimates for all heirs are slightly higher than our estimates (about 1 year higher), presumably because they did not weight their estimates by average bequest.

[^147]:    ${ }^{242}$ Note that it is important to include the $a^{0 c}$ term in the functional form, because in practice the distribution $b_{y}{ }^{c}(a)$ is not exactly centered around mean age $a_{t}{ }^{c}$. This is mostly due to the fact that average bequest varies with heir age. For instance, older children heirs tend to receive slightly bigger bequests, so that the weighted average age of children heirs $\sum_{0 \leq a \leq 80}$ a $b_{t}^{c}(a)$ is slightly larger than $a_{t}^{c}$ by about 2 years. The gap is about 4 years of other heirs. For surviving spouses, the gap is slightly negative: older surving spouses have slightly lower average bequests. All these effects are relatively small quantitatively, but we decide to take them into account in order to fit as closely as possible the observed distribution of heirs age.

[^148]:    ${ }^{243}$ Decomposition by donee category are not available on a yearly basis, but whenever we have data, either through the DMTG micro-files for the 1977-2006 period or through published tabulations for the 1900-1964 period (see e.g. S\&EF déc. $1965 \mathrm{pp} .1698-1699$ ), we find that the children share in the total gift flow is about 97\%-98\%.
    ${ }^{244}$ Available historical data on donors age is limited, so we cannot exclude the possibility of significant historical changes in the age difference between decedents and donors. For the recent period, DMTG-based evidence seems to suggest that this age difference might have been rising somewhat, from about 6 years in the 1977-1984 to about 9 years in 1994-2000; however the most recent data indicates an age difference of 7 years for 2006 (see Table C7), so it is clear whether there is a time pattern or not. In the absence of better data, and as a first approximation, we choose to assume a stable 7-year age difference between dedecents and donors.
    ${ }^{245}$ Our DMTG computations, as well as the most recent published data from the 2006 DMTG survey (see Rapport du Conseil des prélèvements obligatoires, nov.2008, pp. 268 and 279), shows during the 1990s2000s the average age of donees stabilized at about $37-38$ year-old, while on the basis of the rising age of donors and of the age at parenthood of relevant donors' cohorts, it should have increased by about 2 years.

[^149]:    This might be due to the fact that donors have started to give slightly earlier, or to give to slightly younger children. In order to fit the observed age distributions of donors and donees as closely as possible, we assumed a gradual 2.4 -year downward adjustment on the average of donees over the 1994-2006 period; for the pre-1994 and post-2006 period, we just assumed the average age of donees followed the series implied by age of donors and average age at parenthood of the relevant donors' cohors. Computation details are given in do-files dogiftshares.txt and dotableC6.txt.

[^150]:    ${ }^{246}$ See Appendix B, section B2.

[^151]:    ${ }^{247}$ Income tax return micro files are not available prior to the 1970s-1980s, and historical tax tabulations published by the tax administration since 1915 do not break down taxable income by age bracket (only by income bracket). So unfortunately there exists no direct historical data source on age-labor income profiles. ${ }^{248}$ The labor participation rate among the 60-to-69 was about $60 \%-70 \%$ in France in the 1950s-1960s, and then declined quasi linearly to about $20 \%$ in 1995, and then stabilized (and is currently rising somewhat, which does not make a big difference for our profiles, given that replacement rates are very high). See e.g. Bozio (2006, figure 3.1, p.117). So we simply assume a linear downward trend from $100 \%$ in 1910 (when there was virtually no pension system) to $65 \%$ in 1960 and $20 \%$ in 1995 . We assume that nobody works above age 70, and that nobody receives pension income prior to age 60.

[^152]:    ${ }^{249}$ We also attempted to simulate endogenous saving behaviour, as predicted by the utility maximizing models analyzed in sections 5.3 and 5.4 of the working paper (dynastic model and wealth-in-the-utilityfunction model). However the short run and medium run predictions of utility maximizing models are very sensitive to the assumptions one makes about agents' expectations on future growth rates and rates of return, particularly during the chaotic 1914-1945 period (for which it would not make much sense to assume perfect foresight). Also these models generally tend to predict far more age variations in consumption profiles and savings rates than one typically observes (actual age-saving rates profiles are not very far from being flat, just like in the exogenous saving model). In order to obtain plausible predictions, authors using utility maximizing models often end up making simplifying ad hoc assumptions, e.g. they directly assume that the growth rate $g_{c}$ of consumption profiles is the same as the income growth rate $g$ (see for instance Gokhale and Kotlikoff (2001)). Given that there are already so many other effects going on in our two-century-long dynamic model, we find it more natural to simply assume exogenous saving rates, see how much one can explain with such assumptions, and leave the issue of endogenous saving behaviour to future research.

[^153]:    ${ }^{250}$ It is possible that we underestimate somewhat the importance of differential mortality at high age around 1900-1910. But differential mortality would have to be enormous in order to explain such a steeply rising age-wealth profile, which would be consistent with the fact that the fraction of zero-wealth decedents is almost flat (i.e. there seems to be almost as many poor people among the very old decedents than among younger decedents). See Piketty, Postel-Vinay and Rosenthal (2006).

[^154]:    ${ }^{251}$ We use the simulated inheritance flows to do these computations, not the observed flows. Since they are very close, this makes little difference. However we overpredict somewhat the levels of inheritance flows in the 1950s-1960s, this implies that our lifetime resources series tend to overestimate the share of inheritance

[^155]:    in the lifetime resources of the cohorts who inherited in the 1950s-1960s. I.e. the true U-shaped pattern is somewhat more marked than what our series indicate.
    ${ }^{252}$ The fact that we assume the same age-labor income profile throughout the 1820-2008 period (below age 60 ) probably leads us to overestimate the value of $\lambda^{x}$ for the recent cohorts (as compared to $19^{\text {th }}$ century and early $20^{\text {th }}$ century cohorts), and therefore to overestimate the labor share of the lifetime resources of recent cohorts (and underestimate the inheritance share), again relatively to earlier cohorts. It is indeed very likely that the age-labor income profile has become more and more upward sloping over time (i.e. in the $19^{\text {th }}$ century workers in their 20s and 30s were probably not earning much less than workers in their 40 s and 50 s, and in a large number of cases they were actually earning more). I.e. all resources (not only inheritance, but also labor resources) now tend to accrue later in life. Unfortunately we have little systematic information on age-labor income profiles in the $19^{\text {th }}$ century, so we did not try to correct for this.
    ${ }^{253}$ For the benchmark estimates reported on Tables D7-D8, we did not include real rates of capital gains $1+q_{t s}$ into the capitalization factors (i.e. the $1+r_{t s}$ factors only include the normal after-tax rates of return, see do-file). We also re-did all computations with real rates of capital gains: the $\lambda^{x}$ ratio remains very close to $100 \%$, and the shares $\hat{\alpha}^{x}$ and $\psi^{x}$ are virtually unaffected (unless of course one applies capital gains and losses only to inheritance resources; in which case inheritance shares would be substantially larger to the recent period, and substantially lower for the mid- $20^{\text {th }}$ century; but we do not want in this paper to deviate from the assumption of a common rate or return for all individuals and types of ressources). The monetary values $\tilde{b}^{x}$ and $\tilde{y}_{L}{ }^{x}$ however would be affected and would become more volatile and difficult to interpret, for purely artificial reasons (i.e. cohorts who happen to turn 50 in a year with high asset prices would appear as having higher lifetime resources - both inheritance and labor income resources - in euros 2009 than cohorts who happen to turn 50 in a year with low asset prices), so we prefer to present the results this way. The same remarks apply to the rates of capital destructions $1+d_{\text {ts }}$ (which were not included in the benchmark estimates reported on Tables D7-D8. One can easily redo the computations by adding the $q$ and $d$ factors in the corresponding line of the do-file.
    ${ }^{254}$ See formulas in excel file.
    ${ }^{255}$ Namely, we assume that the inverted Pareto coefficient is equal to 5 for cohorts 1820-1870 and equal to 3 for cohorts 1930-2030 (and declined linearly in between), which approximately corresponds to the observed

[^156]:    values at the $90^{\text {th }}$ percentile level (see Piketty et al (2006, data appendix, Tables A3-A6)). See formulas in excel file. In order to obtain a better fit, one should use type-2 Pareto distributions for wealth distributions rather than type-1 Pareto distributions. But here this would have little effect on the pattern of $\varepsilon^{x}$.

[^157]:    ${ }^{256}$ If we were only adjusting for consumer price inflation $1+p_{s t}$, then the corresponding wealth shares $\varphi_{t}{ }^{\text {M }}$ would be artificially high following periods of relative asset price decline (such as the 1950s-1960s). For the same reason, we also adjust past bequest and gift flows by cumulated capital destruction rates $1+\mathrm{d}_{\text {st }}$ (otherwise the corresponding wealth shares $\varphi_{t}^{M}$ would be artificially high following war periods: in effect we would be including in inherited wealth assets that were destroyed during wars). One can easily redo the computations by adding or substracting the $\mathrm{p}, \mathrm{q}$ and d factors in the corresponding line of the do-file.

[^158]:    ${ }^{257}$ See formulas (7.6)-(7-7) (working paper, section 7.3) and Table E12 for illustrative computations.

[^159]:    ${ }^{258}$ With $\mathrm{H}=30, \mathrm{~g}=1.7 \%$, and $(1-\mathrm{T}) \mathrm{r}=3.0 \%$, the theoretical steady-state capitalization factor should be $207 \%$ (see Table E12), and we find that the average capitalization factor converges towards about 195\% during the $21^{\text {st }}$ century (see Table D9). With $\mathrm{H}=30, \mathrm{~g}=1.0 \%$ and ( $\left.1-\mathrm{T}\right) \mathrm{r}=5.0 \%$, the theoretical level is $269 \%$ (see Table E12), and we find convergence towards $350 \%$ during the $21^{\text {st }}$ century (see Table D10).

[^160]:    ${ }^{259}$ Here we implicitly assume that the aggregate wealth accumulation process has already converged, i.e. $\beta_{t}=w_{t} / y_{t}$ is permanently equal to $\beta^{*}=\mathrm{s} / \mathrm{g}$, so that $w_{t}$ and $y_{t}$ grow exactly at rate g . Otherwise one could not replace $s_{L} y_{L t} /\left(g-s_{K} r^{*}\right)$ by $w_{t}$. and the transition equation for $\mu_{t}$ would look more complicated.
    ${ }^{260}$ We used the following parameters for Figures E1-E2 (see formulas in excel file): $A=20, H=30, D=70,1-$ $\alpha=70 \%$. We assumed uniform savings (in which case s has no impact on age-wealth profiles). With $\mathrm{g}=2 \%$, we get $\mu^{*}=147 \%$ (see Figure E1); with $g=5 \%$ we get $\mu^{*}=127 \%$ (see Figure E2).
    ${ }^{261}$ The fact that growth effects can mechanically deliver hump-shaped cross-sectional profiles, even in the absence of any lifecycle saving behaviour, was first pointed out by Shorrocks (1975). Here however the growth effect comes from inheritance (older individuals are poorer because they received lower bequest) rather than from labor income: with $\rho=1$ older individuals have the same labor income as younger ones.

[^161]:    When we introduce $\rho<1$, then the Shorrocks labor income effect shows up (older indidivuals are poorer because they do not fully benefit from labor income growth), which reinforces the total growth effect and makes the cross-sectional profile even more hump-shaped (see below).

[^162]:    ${ }^{262}$ The values for $\mu^{*}=\mu(\mathrm{g}, \rho)$ reported in Table E1 apply for all savings rates $s_{K}$ and $s_{L}$ (all what matters for $\mu^{*}=\mu(\mathrm{g}, \mathrm{\rho})$ is the relative share of labor income savings in total savings (1- $\alpha$ ) $\left.\mathrm{s}_{\mathrm{L}} / \mathrm{s}\right)$. In order to illustrate the impact of $\mu^{*}$ on $b_{y}{ }^{*}$, we also report the corresponding $b_{y}{ }^{*}=\mu^{*} m^{*} \beta^{*}$ assuming a fixed $\beta^{*}=600 \%$ (this is implicitly assuming that levels of $s_{K}$ and $s_{\llcorner }$adapt to changes in $g$ so as to keep $\beta^{*}$ constant; this allows us to focus upon the pure age profile effect on $b_{y}{ }^{*}$, shutting down the aggregate wealth accumulation $\beta^{*}$ effect).

[^163]:    ${ }^{263}$ Here we refer to $b_{y t}=\mu_{t} m_{t} \beta_{t}$, i.e. to the inheritance flow-national income ratio. If we were instead using domestic income as the denominator, then the inheritance-income ratio would naturally $\rightarrow+\infty$ in the case $r>\infty$ (in the same way as in the wealth-in-utility-function model, see below).
    ${ }^{264}$ The values for $\mu^{*}=\mu(\mathrm{g}, \mathrm{r})$ reported in Table E2 were computed for a fixed $\mathrm{s}_{\kappa}$ and for $\rho=1$. In order to illustrate the impact of $\mu^{*}$ on $b_{y}{ }^{*}$, we again report the corresponding $b_{y}{ }^{*}=\mu^{*} m^{*} \beta^{*}$ assuming a fixed $\beta^{*}=600 \%$ (this is implicitly assuming that $\mathrm{s}_{\mathrm{L}}$ adapt to changes in g so as to keep $\beta^{*}$ constant).
    ${ }^{265}$ Here we write wealth and consumption equations at the aggregate cohort level, but because of linearity they are exactly the same at the same at the individual level (i.e. everything applies proportionally to each dynasty i with inheritance $\mathrm{b}_{\mathrm{i}}{ }^{\mathrm{x}}$ within cohort x ). Also note that we do not need to worry about labor income since with $\rho=1$ it is entirely consumed (irrespective of the bequest level, again because of linearity).

[^164]:    ${ }^{266}$ Parents derive utility only from what their children consume after age $I$; but children also care about what they consume between age A and age I; in perfect foresight steady-states, parents end up internalizing this borrowing behavior (this is of course assuming that parents cannot disallow their children to borrow against inheritance, which does not seem very realistic; see discussion in working paper, section 7.3).

[^165]:    ${ }^{267}$ We used the following parameters for Figure E4 (see formulas in excel file): $A=20, H=30, D=70, g=2 \%$, $r^{*}=5 \%$. Applying the formulas we get $\bar{\mu}=167 \%$ (no borrowing) and $\mu^{*}=239 \%$.

[^166]:    ${ }^{268}$ If we instead assume perfect foresight on inheritance receipts and full maximization at age A, then individuals with high expected inheritance will save less between age A and I (and possibly not at all) than the formulas below (which would only apply to individuals with zero inheritance). This might be relevant empirically (borrowing against future inheritance is difficult in practice, but lowering saving is easy). So the formulas below should be viewed as an upper bound for lifecycle wealth.
    ${ }^{269}$ We look at steady-state paths ( $r^{*}=r+\theta \sigma$ ), so the desired consumption growth rate $g_{c}=(r-\theta) / \sigma$ is equal to g .
    ${ }^{270}$ Here we again write wealth and consumption equations at the aggregate cohort level, but because of linearity they are exactly the same at the same at the individual level (i.e. everything applies proportionally to each dynasty i with labor income $\mathrm{y}_{\mathrm{L}}$ within cohort x ). Again because of linearity we can look separately at lifecycle wealth and forget about bequest wealth.

[^167]:    ${ }^{271}$ See e.g. Modigliani (1986). The intuition for this well known formula is very simple: at the top of their wealth accumulation trajectory (at age $a=R$ ), lifecycle savers need to own the equivalent of D-R years of labor income in order to finance retirement consumption; by linearity, individuals on the rising and declining segments of the triangle (below and above age $a=R$ ) own on average ( $D-R$ )/2 years. The reason why ( $D-R$ )/2 needs to be multiplied by ( $R-A$ )/(D-A) is because we divide lifecycle wealth $w_{L t}$ by per adult labor income $y_{L t}$ (rather than by per worker labor income=(D-A) $\left.y_{L_{t}} /(R-A)\right)$. This makes more sense from an aggregate wealth accumulation viewpoint. So for instance if $R$ is fixed and $D$ goes to infinity, then $\bar{\beta}_{L} \rightarrow(R-A) / 2$ (not to infinity).

[^168]:    ${ }^{272}$ Intuitively, this is because a rise in $\mathrm{r}^{*}$-g makes everybody richer (workers now receive labor income and capital income, while with $r^{\star}=g=0$ there was no capital income at all, i.e. saving was a pure storage technology); to obtain given absolute living standards during retirement, workers could afford accumulating a lot less lifecycle wealth; but because they seek the have the same relative consumption during work and retirement years, lifecycle wealth does not decline all that much as $r^{*}$-g rises.

[^169]:    ${ }^{273}$ We again report the corresponding $b_{y}{ }^{*}=\mu^{*} m^{*} \beta^{*}$ assuming a fixed $\beta^{*}=600 \%$ (this is implicitly assuming that $\theta$ adapts to changes in g so as to keep $\beta^{*}$ constant).
    ${ }^{274}$ We use the following parameters for Figures E5-E8 (see formulas in excel file): $A=20, H=30, R=60, D=80$, $g=2 \%, r^{*}=5 \%$. Applying the formulas we get $\mu^{*}=173 \%$ ( $\rho=80 \%$ ), $\mu^{*}=134 \% ~\left(~ \rho=50 \%\right.$ ) and $\mu^{*}=67 \% ~(~ \rho=0 \%)$ (see Table E4).
    ${ }^{275}$ See Table A3 for detailed computations on the lifecycle wealth share. Note that this is true both a given $\mathrm{r}^{*}$ (a rise in $g$ then implies a fall in $r^{\star}-g$, and therefore a rise in $\bar{\beta}_{L}$ ), and for an endogenous $r^{*}=\theta+\sigma g$ : a rise in $g$ then leads to a rise in $r^{*}-\mathrm{g}$ (assuming $\sigma>1$ ) and a decline in $\bar{\beta}_{L}$, but the rise in $r^{*}$ means an even bigger decline in $\beta^{*}$, so that the lifecycle wealth share rises. Note also that for extreme parameter values ( g above $4 \%-5 \%$, endogenous $r^{*}$ above $10 \%$ ), then lifecycle wealth may exceed aggregate wealth: strictly speaking this would imply negative bequests, i.e. borrowing from future generations, but this is impossible.

[^170]:    ${ }^{276} \mathrm{In}$ case $\mathrm{g}_{\mathrm{c}}=\mathrm{g}$ (i.e. in case $\mathrm{r}=\hat{\mathrm{r}}$, where $\hat{\mathrm{r}}=\theta+\sigma \mathrm{g}$ is the dynastic model steady-state rate of return), then $s_{L}=s_{B}$. However in the wealth-in-the-utility-function model there is no reason why $r$ should be equal to $\hat{r}$ : the closed-economy steady-state $r$ can be larger or smaller than $\hat{r}$ depending on the value of $s_{B}$ (see below).
    ${ }^{277}$ We use the same open economy notations as those introduced in the proof of proposition 4 (see above).

[^171]:    278 See Tables E6 and E7 below.

[^172]:    ${ }^{279}$ This is partly due to the specific functional form we use for utility functions: the utility value of lifetime consumption flows $U_{C}$ is proportional to capitalized end-of-life consumption $\tilde{c}$, so the log form for $\mathrm{V}\left(\mathrm{U}_{\mathrm{c}}, \mathrm{w}(\mathrm{D})\right.$ ) implies that the multiplicative term does not matter. I.e. the marginal utility derived from extra $\tilde{c}$ does not depend on the length of time available to consume $\tilde{c}$. So for instance even if one cannot consume inheritance before age I (i.e. no borrowing), agents will keep consuming the same fraction of their bequest $\left(1-s_{B}\right) b^{x} e^{r H}$, no matter how short the time span D-I left for consumption. With other functional forms (e.g. CES), one would get consumption time effects, and typically agents would end up consuming a lower fraction of their bequest in the no-borrowing case. In effect, the $\mathrm{s}_{\mathrm{B}}$ factor will be higher for inheritance resources than for labor resources, which might be more realistic (see e.g. Masson (1988)). A higher $\mathrm{s}_{\mathrm{B}}$ for inheritance resources could also be due to the fact that individuals might feel less comfortable eating up a large fraction of their inherited resources rather than eating up a large fraction of the product of their own labor. Here we adopt standard preferences with a single budget constraint (no separate mental account), so agents treat both types of resources identically.

[^173]:    ${ }^{280}$ There are several reasons why $g_{c}$ is usually relatively close to $g$ in the real world, i.e. why consumption tends to track income much more closely that what optimising models tend to predict. First, agents might not know in advance that g is going to be equal to $5 \%$ in the next 30 years (e.g. it was pretty hard to predict in the 1930s-1940s that $g$ was going to be $5 \%-6 \%$ in the $1950 \mathrm{~s}-1960 \mathrm{~s}$ ), so they might adjust consumption growth to current growth. Next, even if they know in advance that $\mathrm{g}=5 \%$ and their preference parameters are such that they want a lot of consumption smoothing (say $\mathrm{g}_{\mathrm{c}}=1 \%$ ) they might face borrowing constraints.

[^174]:    ${ }^{281}$ It is not really meaningful to push further the pension analysis without modelling explicitly the reason why pay-as-you-go systems were introduced in the first place (i.e. uninsurable uncertainty on r).
    ${ }^{282}$ E.g. in the class saving case (Proposition 2), then if I=D-H<A the steady-state age-wealth profile (incl. children) would now be : $w_{t}(a)=0$ if $a \in[0 ; I]$ and $w_{t}(a)=b_{t}$ if $a \in[I ; D]$, so that $\mu^{*}=b_{t} / w_{t}=D /(D-I)=D / H$. Since the mortality rate (incl. children) is now given by $m^{*}=1 / D$, we again obtain $b_{w}{ }^{*}=\mu^{*} m^{*}=1 / H$ and $b_{y}{ }^{*}=\beta^{*} / H$. I.e. the basic result is unchanged. In order to fully solve the models with endogenous saving, one would need however to make assumptions as to whether children inheritors are allowed to borrow against future labor resources or are under the control of other family members until adulthood.

[^175]:    ${ }^{283}$ We set initial cohort size $\mathrm{N}^{0}$ equal to 1 .
